

Digital Personalized Health and Medicine

Proceedings of MIE 2020

Editors: Louise B. Pape-Haugaard
Christian Lovis
Inge Cort Madsen
Patrick Weber
Per Hostrup Nielsen
Philip Scott

Digital health and medical informatics have grown in importance in recent years, and have now become central to the provision of effective healthcare around the world.

This book presents the proceedings of the 30th Medical Informatics Europe conference (MIE). This edition of the conference, hosted by the European Federation for Medical Informatics (EFMI) since the 1970s, was due to be held in Geneva, Switzerland in April 2020, but as a result of measures to prevent the spread of the Covid19 pandemic, the conference itself had to be cancelled.

Nevertheless, because this collection of papers offers a wealth of knowledge and experience across the full spectrum of digital health and medicine, it was decided to publish the submissions accepted in the review process and confirmed by the Scientific Program Committee for publication, and these are published here as planned. The 232 papers are themed under 6 section headings: biomedical data, tools and methods; supporting care delivery; health and prevention; precision medicine and public health; human factors and citizen centered digital health; and ethics, legal and societal aspects. A 7th section deals with the Swiss personalized health network, and section 8 includes the 125 posters accepted for the conference.

Offering an overview of current trends and developments in digital health and medical informatics, the book provides a valuable information resource for researchers and health practitioners alike.

DIGITAL PERSONALIZED HEALTH AND MEDICINE

Studies in Health Technology and Informatics

International health informatics is driven by developments in biomedical technologies and medical informatics research that are advancing in parallel and form one integrated world of information and communication media and result in massive amounts of health data. These components include genomics and precision medicine, machine learning, translational informatics, intelligent systems for clinicians and patients, mobile health applications, data-driven telecommunication and rehabilitative technology, sensors, intelligent home technology, EHR and patient-controlled data, and Internet of Things.

Studies in Health Technology and Informatics (HTI) series was started in 1990 in collaboration with EU programmes that preceded the Horizon 2020 to promote biomedical and health informatics research. It has developed into a highly visible global platform for the dissemination of original research in this field, containing more than 250 volumes of high-quality works from all over the world.

The international Editorial Board selects publications with relevance and quality for the field. All contributions to the volumes in the series are peer reviewed.

Volumes in the HTI series are submitted for indexing by MEDLINE/PubMed; Web of Science: Conference Proceedings Citation Index – Science (CPCI-S) and Book Citation Index – Science (BKCI-S); Google Scholar; Scopus; EMCare.

Series Editors:

B. Blobel, O. Bodenreider, E. Borycki, M. Braunstein, C. Bühler, J.P. Christensen, R. Cooper, R. Cornet, J. Dewen, O. Le Dour, P.C. Dykes, A. Famili, M. González-Sancho, E.J.S. Hovenga, J.W. Jutai, Z. Kolitsi, C.U. Lehmann, J. Mantas, V. Maojo, A. Moen, J.F.M. Molenbroek, G. de Moor, M.A. Musen, P.F. Niederer, C. Nøhr, A. Pedotti, N. Peek, O. Rienhoff, G. Riva, W. Rouse, K. Saranto, M.J. Scherer, S. Schürer, E.R. Siegel, C. Safran, N. Sarkar, T. Solomonides, E. Tam, J. Tenenbaum, B. Wiederhold, P. Wilson and L.H.W. van der Woude

Digital Personalized Health and Medicine: Preface

Philip SCOTT^a and Louise B. PAPE-HAUGAARD^b

^a*School of Computing, University of Portsmouth, United Kingdom*

^b*Dept of Health Science and Technology, Aalborg University, Denmark*

This volume presents the proceedings of the 30th Medical Informatics Europe conference (MIE), organized in Geneva, Switzerland, in April 2020. This collection of papers offers a wealth of knowledge and experience across the full spectrum of digital health and medicine.

MIE conferences have been hosted by the European Federation for Medical Informatics (EFMI) since the 1970s. Over those decades, we have been privileged to share in a growing community of expertise in health and care informatics and seen the advancement of the field from a few pioneers to a diverse international network.

The overarching concept of Digital Personalized Health and Medicine is elaborated under the six programme themes as the structure of this volume:

- Biomedical data, tools and methods
- Supporting care delivery
- Health and prevention
- Precision medicine and public health
- Human factors and citizen centered digital health
- Ethics, legal and societal aspects

The topics of the conference proceedings demonstrate that crucial scientific work is still in progress across this scientific continuum and that much existing knowledge is yet to be widely adopted in routine practice. For example, recent years have seen unprecedented leaps forward in data science and machine learning, yet important work still continues on basic prerequisites such as data quality and computable semantic interoperability. Further excellent work continues in human-computer interaction, policy, workforce development, ethics and regulation. Increasing attention is being paid to citizen and patient concerns, whether it be trust in computerised clinical guidance, privacy and consent or issues of safety and accountability.

Helpfully, the Learning Health System is increasingly seen as a unifying concept for basic and translational health and care informatics, incorporating standards for representing biomedical knowledge, machine learning, precision medicine, clinical decision support systems, quality improvement and behaviour change.

We commend this body of papers to readers as a powerful educational resource.

MIE 2020 was organized in partnership with the World Health Organization (WHO), the International Telecommunication Union (ITU), the State of Geneva (Geneva), the University of Geneva (UNIGE) and the University Hospitals of Geneva (HUG). The local team would particularly like to acknowledge the work of Dr Vasiliki Foufi PhD and Christophe Gaudet-Blavignac BSc CS MMed. The editors would like to express thanks to our doctoral student assistants, Taiwo Adedeji MSc and Obinwa Ozonze MSc.

***On behalf of EFMI, the Scientific Program Committee and the Editors of the
Proceedings of MIE2020***

1. Message from EFMI

In regard with the fast evolving situation due to the pandemic of coronavirus, the absolute necessity to slow down the progression of the spread of the virus to avoid collapse of the care systems, the State of Emergency has been decided by the Swiss Federal Council, implementing a locked down of the country. The global situation, has thus led to cancel the MIE2020 Conference.

MIE2020's primary concern is the safety of both participants, sponsors, committees and all of those who had planned to attend the Congress along with the investment that all have made to be present.

It has been decided to publish the Proceedings. Submissions accepted in the review process and confirmed by the SPC for publication will be published and indexed as planned.

The Editors of the Proceedings thank IOS Press for their support in this difficult situation.

Editorial Assistants and Reviewers for MIE2020

Editorial Assistant Acknowledgements

The editors would like to gratefully acknowledge the assistance of our colleagues in final preparation of the manuscripts for publication.

Adedeji, Taiwo

Nakkas, Haythem

Ozonze, Obinwa

Foufi, Vasiliki, Dr. PhD

Gaudet-Blavignac, Christophe, BSc CS, MMed

Reviewers

The editors would also like to gratefully thank the reviewers who have contributed in the reviewing phase. Without these reviews we would not be able to have so high standards.

Part 1

Section 1. Biomedical Data, Tools and Methods

A FHIR-Based eConsent App for the Digital Hospital	3
<i>Manuela Weber, Alexandra Griessbach, Regina Grossmann and Jürg Blaser</i>	
A Secure Multi-Party Computation Protocol for Time-To-Event Analyses	8
<i>Lennart Vogelsang, Moritz Lehne, Phillipp Schoppmann, Fabian Prasser, Sylvia Thun, Björn Scheuermann and Josef Schepers</i>	
A Semantic Similarity Evaluation for Healthcare Ontologies Matching to HL7 FHIR Resources	13
<i>Athanasios Kiourtis, Argyro Mavrogiorgou and Dimosthenis Kyriazis</i>	
A Semi-Automated Approach for Multilingual Terminology Matching: Mapping the French Version of the ICD-10 to the ICD-10 CM	18
<i>Emmanuelle Sylvestre, Guillaume Bouzillé, Michael McDuffie, Emmanuel Chazard, Paul Avillach and Marc Cuggia</i>	
An Automatic Image Collection System for Multicenter Clinical Studies	23
<i>Toshihiro Takeda, Shirou Manabe, Atsushi Hattori, Junji Yamaguchi, Shozo Konishi, Yuichiro Yamamoto, Daiyo Takahashi and Yasushi Matsumura</i>	
An Evolutionary Approach to the Annotation of Discharge Summaries	28
<i>Christina Lohr, Luise Modersohn, Johannes Hellrich, Tobias Kolditz and Udo Hahn</i>	
Application of Radiomics in Vesselness Analysis of CT Angiography Images of Stroke Patients	33
<i>Daria Dolotova, Ivan Arkhipov, Evgenia Blagosklonova, Victoria Donitova, Tatiana Barmina, Faat Sharifullin, Boris Kobrinskii and Andrey Gavrilov</i>	
Automated Mapping of LEP Nursing Data to Nursing Minimum Data Sets	38
<i>Renate Ranegger, Werner O. Hackl, Inge Eberl, Dieter Baumberger, Reto Bürgin and Elske Ammenwerth</i>	

Automated Spelling Correction for Clinical Text Mining in Russian <i>Ksenia Balabaeva, Anastasia Funkner and Sergey Kovalchuk</i>	43
Automatic Classification of Discharge Letters to Detect Adverse Drug Reactions <i>Vasiliki Foufi, Kuntheavy Ing Lorenzini, Jean-Philippe Goldman, Christophe Gaudet-Blavignac, Christian Lovis and Caroline Samer</i>	48
Automatic Extraction of Risk Factors for Dialysis Patients from Clinical Notes Using Natural Language Processing Techniques <i>George Michalopoulos, Hammad Qazi, Alexander Wong, Zahid Butt and Helen Chen</i>	53
Automating Quality Control for Structured Standardized Radiology Reports Using Text Analysis <i>Anjani Dhrangadhariya, Sandy Millius, Cyril Thouly, Benoit Rizk, Dominique Fournier, Henning Müller and Hugues Brat</i>	58
Bank of Digital Filters for Identification of Combined Drug Products in a French Public Database <i>Adrien Ugon, Mélanie Courtine, Karima Sedki, Pierre Quentin, Marion Valette and Rosy Tsopra</i>	63
Better Safe than Sorry – Implementing Reliable Health Data Anonymization <i>Raffael Bild, Klaus A. Kuhn and Fabian Prasser</i>	68
Blood Lactate Concentration Prediction in Critical Care <i>Behrooz Mamandipoor, Mahshid Majd, Monica Moz and Venet Osmani</i>	73
Building an I2B2-Based Population Repository for Clinical Research <i>Lydia González, David Pérez-Rey, Enrique Alonso, Gema Hernández, Pablo Serrano, Miguel Pedrera, Agustín Gómez, Kristof De Schepper, Titus Crepain and Brecht Claerhout</i>	78
Character-Level Neural Language Modelling in the Clinical Domain <i>Markus Kreuzthaler, Michel Oleynik and Stefan Schulz</i>	83
Clinical Abbreviation Disambiguation Using Deep Contextualized Representation <i>Mingkai Peng and Hude Quan</i>	88
Clinical Concept Normalization on Medical Records Using Word Embeddings and Heuristics <i>João Figueira Silva, Rui Antunes, João Rafael Almeida and Sérgio Matos</i>	93
Clinical History Segment Extraction from Chronic Fatigue Syndrome Assessments to Model Disease Trajectories <i>Sonia Priou, Natalia Viani, Veshalee Vernugopan, Chloe Tytherleigh, Faduma Abdalla Hassan, Rina Dutta, Trudie Chalder and Sumithra Velupillai</i>	98
Clinico-Environmental System for Personal Monitoring <i>Filipe Pires, André Pedrosa, João Alegria and Carlos Costa</i>	103

Cohort Creation and Visualization Using Graph Model in the PREDIMED Health Data Warehouse	108
<i>Christophe Cancé, Pierre-Ephrem Madiot, Christian Lenne, Svetlana Artemova, Brigitte Cohard, Marjolaine Bodin, Alban Caporossi, Jean-François Blatier, Jérôme Fauconnier, Frédérique Olive, Daniel Pagonis, Dominique Le Magny, Jean-Luc Bosson, Katia Charriere, Ivan Paturel, Bruno Lavaire, Gabriel Schummer, Joseph Eterno, Jean-Noël Ravey, Ivan Bricault, Gilbert Ferretti, Sébastien Chanoine, Pierrick Bedouch, Emmanuel Barbier, Julien Thevenon, Pascal Mossuz and Alexandre Moreau-Gaudry</i>	
Commercial Adoption of AI in the Healthcare Sector: An Exploratory Analysis of S&P500 Companies	113
<i>Tomasz Mucha, Olli Halminen, Henni Tenhunen and Timo Seppälä</i>	
A Computational Adverse Event Detection Matrix	118
<i>Mary Gadde and Melody Penning</i>	
Computer-Assisted Quality Assessment of Aortic CT Angiographies for Patient-Individual Dose Adjustment	123
<i>Marja Fleitmann, Kira Soika, Andreas Martin Stroth, Jan Gerlach, Alexander Fürschke, Peter Hunold, Jörg Barkhausen, Arpad Bischof and Heinz Handels</i>	
Continuous Monitoring and Statistical Modelling of Heart Rate Variability	128
<i>Adina Nitulescu, Mihaela Crisan-Vida and Lacramioara Stoicu-Tivadar</i>	
Data Fusion to Convert Drug Consumption Quantities into Defined Daily Doses	133
<i>Adrien Ugon, Sabine Guessant and Rosy Tsopra</i>	
Data Integration into OMOP CDM for Heterogeneous Clinical Data Collections via HL7 FHIR Bundles and XSLT	138
<i>Patrick Fischer, Mark R. Stöhr, Henning Gall, Achim Michel-Backofen and Raphael W. Majeed</i>	
Data Quality Challenges in a Learning Health System	143
<i>Michail Sarafidis, Marilena Tarousi, Athanasios Anastasiou, Stavros Pitoglou, Efstratios Lampoukas, Athanasios Spetsarias, George Matsopoulos and Dimitrios Koutsouris</i>	
De-Identifying Swedish EHR Text Using Public Resources in the General Domain	148
<i>Taridzo Chomutare, Kassaye Yitbarek Yigzaw, Andrius Budrionis, Alexandra Makhlysheva, Fred Godtliebsen and Hercules Dalianis</i>	
Deep Learning for Accurate Diagnosis of Glaucomatous Optic Neuropathy Using Digital Fundus Image: A Meta-Analysis	153
<i>Mohaimenul Islam, Tahmina Nasrin Poly, Hsuan Chia Yang, Suleman Atique and Yu-Chuan Jack Li</i>	

Design for a Modular Clinical Trial Recruitment Support System Based on FHIR and OMOP	158
<i>Ines Reinecke, Christian Gulden, Michéle Kümmel, Azadeh Nassirian, Romina Blasini and Martin Sedlmayr</i>	
Detection of Muscle Weakness in Medical Texts Using Natural Language Processing	163
<i>Gleb Danilov, Michael Shifrin, Yuliya Strunina, Konstantin Kotik, Tatyana Tsukanova, Tatiana Pronkina, Timur Ishankulov, Elizaveta Makashova, Alexandra Kosyrkova and Alexander Potapov</i>	
Digitalisation of the Brief Visuospatial Memory Test-Revised and Evaluation with a Machine Learning Algorithm	168
<i>Martin Eduard Birchmeier, Tobias Studer, Andreas Lutterotti, Iris-Katharina Penner and Serge Bignens</i>	
Discovering New Social Determinants of Health Concepts from Unstructured Data: Framework and Evaluation	173
<i>Joao H. Bettencourt-Silva, Natalia Mulligan, Marco Sbodio, John Segrave-Daly, Richard Williams, Vanessa Lopez and Carlos Alzate</i>	
Distinguishing Septal Heart Defects from the Valvular Regurgitation Using Intelligent Phonocardiography	178
<i>Arash Gharehbaghi, Amir A. Sepehri and Ankica Babic</i>	
Document Oriented Graphical Analysis and Prediction	183
<i>Shorabuddin Syed, Mahanazuddin Syed, Hafsa Bareen Syeda, Fred Prior, Meredith Zozus, Melody L. Penning and Mohammed Orloff</i>	
Electronic Whiteboard in the Inpatient Care Management: Nurses' Perceptions About the Use	188
<i>Liliana Giraldo, Bibiana Schachner, Daniel Luna and Sonia Benitez</i>	
Efficient Protection of Health Data from Sensitive Attribute Disclosure	193
<i>Raffael Bild, Johanna Eicher and Fabian Prasser</i>	
Emerging Concepts and Applied Machine Learning Research in Patients with Drug-Induced Repolarization Disorders	198
<i>Mina Bjelogrljic, Arnaud Robert, Arnaud Miribel, Mehdi Namdar, Baris Gencer, Christian Lovis and François Girardin</i>	
End-to-End Approach for Structuring Radiology Reports	203
<i>Kento Sugimoto, Toshihiro Takeda, Shoya Wada, Asuka Yamahata, Shozo Konishi, Shiro Manabe and Yasushi Matsumura</i>	
Evaluation of Document Retrieval Systems on a Medical Corpus in French: Indexation vs. Feature Learning	208
<i>Arnaud Robert, Francis Damachi, Mina Bjelogrljic, Jean-Philippe Goldman and Christian Lovis</i>	
Evaluation of the Quality of French Hospital Data for Perinatal Algorithms	213
<i>Karine Goueslard, Jonathan Cottenet, Eric Benzenine, Pascale Tubert-Bitter and Catherine Quantin</i>	

Exploring Patient Path Through Sankey Diagram: A Proof of Concept <i>Antoine Lamer, Gery Laurent, Sylvia Pelayo, Mehdi El Amrani, Emmanuel Chazard and Romaric Marcilly</i>	218
Extending Contsys Standard with Social Care Concepts: A Methodology Proposed by the UNINFO Working Group in Italy <i>Fabrizio Pecoraro, Daniela Luzi, Elaheh Pourabbas, Fabrizio L. Ricci and Angelo Rossi Mori</i>	223
Feasibility of Using EN 13606 Clinical Archetypes for Defining Computable Phenotypes <i>Archana Tapuria, Dipak Kalra and Vasa Curcin</i>	228
Generation of Fine Grained Demographic Information for Epidemiological Analysis <i>Timo Wolters, Oke Wübbenhorst, Christian Lüpkes and Andreas Hein</i>	233
GenoShare: Supporting Privacy-Informed Decisions for Sharing Individual-Level Genetic Data <i>Jean Louis Raisaro, Juan Ramón Troncoso-Pastoriza, Yamane El-Zein, Mathias Humbert, Carmela Troncoso, Jacques Fellay and Jean-Pierre Hubaux</i>	238
H-Accuracy, an Alternative Metric to Assess Classification Models in Medicine <i>Andrea Campagner, Luca Sconfienza and Federico Cabitza</i>	242
Heimdall, a Computer Program for Electronic Health Records Data Visualization <i>Niels Martignene, Thibaut Balcaen, Guillaume Bouzille, Matthieu Calafiore, Jean-Baptiste Beuscart, Antoine Lamer, Bertrand Legrand, Grégoire Ficheur and Emmanuel Chazard</i>	247
How Have Experimental Cancer Interventions Evolved over Time? <i>Ziran Li, Huanyao Chen, Chi Yuan and Chunhua Weng</i>	252
Impact of Altering Data Granularity Levels on Predictive Modelling: A Case Study of Fall Risk Prediction in Older Persons <i>Noman Dormosh, Ameen Abu-Hanna, Nathalie van der Velde and Martijn Schut</i>	257
Incorporation of Multiple Sources into IT – and Data Protection Concepts: Lessons Learned from the FARKOR Project <i>Doris Lindoerfer, Ulrich Mansmann and Isabel Reinhardt</i>	262
Integrating the Comparative Toxicogenomic Database in a Human Pharmacogenomic Resource <i>François-Élie Calvier and Cedric Bousquet</i>	267
Integration of Unstructured Data into a Clinical Data Warehouse for Kidney Transplant Screening – Challenges & Solutions <i>Maximilian Zubke, Matthias Katzensteiner and Oliver J. Bott</i>	272

Interpretation Method for Continuous Glucose Monitoring with Subsequence Time-Series Clustering	277
<i>Masaki Ono, Takayuki Katsuki, Masaki Makino, Kyoichi Haida and Atsushi Suzuki</i>	
Introducing New Measures of Inter- and Intra-Rater Agreement to Assess the Reliability of Medical Ground Truth	282
<i>Andrea Campagner and Federico Cabitza</i>	
Learning Scan Paths of Eye Movement in Autism Spectrum Disorder	287
<i>Meenakshi Chatterjee, Nikolay V. Manyakov, Abigail Bangerter, Dzmitry A. Kaliukhovich, Shyla Jagannatha, Seth Ness and Gahan Pandina</i>	
Leveraging PubMed to Create a Specialty-Based Sense Inventory for Spanish Acronym Resolution	292
<i>Alexandra Pomares-Quimbaya, Pilar López-Úbeda, Michel Oleynik and Stefan Schulz</i>	
Logical Rules and a Preliminary Prototype for Translating Mortality Coding Rules from ICD-10 to ICD-11	297
<i>Vincenzo Della Mea, Mihai H. Popescu, Francesco Grippo, Chiara Orsi and Friedrich Heuser</i>	
Machine Learning Assisted Citation Screening for Systematic Reviews	302
<i>Anjani Dhrangadhariya, Roger Hilfiker, Roger Schaer and Henning Müller</i>	
Machine Learning Explainability in Breast Cancer Survival	307
<i>Tom Jansen, Gijs Geleijnse, Marissa Van Maaren, Mathijs P. Hendriks, Annette Ten Teije and Arturo Moncada-Torres</i>	
Machine Learning for Automatic Encoding of French Electronic Medical Records: Is More Data Better?	312
<i>Julien Gobeill, Patrick Ruch and Rodolphe Meyer</i>	
MedCo ² : Privacy-Preserving Cohort Exploration and Analysis	317
<i>David Froelicher, Mickaël Misbach, Juan R. Troncoso-Pastoriza, Jean Louis Raisaro and Jean-Pierre Hubaux</i>

VIVID: Independent Living of Aging Adults Suffered a Stroke <i>Athanasios Anastasiou, Ourania Manta, Dimitra Iliopoulou and Dimitrios Koutsouris</i>	509
Section 2. Supporting Care Delivery	
A Domain-Independent Semantically Validated Authoring Tool for Formalizing Clinical Practice Guidelines <i>Jordi Torres, Garazi Artola and Naiara Muro</i>	517
A Process Mining Application for the Analysis of Hospital-at-Home Admissions <i>Ilaria Angela Amantea, Emilio Sulis, Guido Boella, Renata Marinello, Dario Bianca, Enrico Brunetti, Mario Bo and Carlos Fernandez-Llatas</i>	522

An Albanian Text-to-Speech System for the BabelDr Medical Speech Translator <i>Nikos Tsourakis, Rovena Troqe, Johanna Gerlach, Pierrette Bouillon and Hervé Spechbach</i>	527
Are Clinical Decision Support Systems Compatible with Patient-Centred Care? <i>Vije Kumar Rajput, Jack Dowie and Mette Kjer Kaltoft</i>	532
Case-Based Reasoning for Support of the Diagnostics of Cardiovascular Diseases <i>Zuzana Tocimáková, Ludmila Pusztová, Ján Paralič and Dominik Pella</i>	537
Clinical Decision Support Systems in Nursing Homes: A Scoping Review <i>Abir Abdellatif, Jacques Bouaud, Duy Nghiem, Carmelo Lafuente-Lafuente, Joël Belmin and Brigitte Séroussi</i>	542
Comparison of Unplanned 30-Day Readmission Prediction Models, Based on Hospital Warehouse and Demographic Data <i>Thibault Dhalluin, Aurélie Bannay, Pierre Lemordant, Emmanuelle Sylvestre, Emmanuel Chazard, Marc Cuggia and Guillaume Bouzille</i>	547
Cross-Border Exchange of Clinical Data Using Archetype Concepts Compatible with the International Patient Summary <i>Dimitar Tcharaktchiev, Evgeniy Krastev, Patrick Petrossians, Simeon Abanos, Hristo Kyurkchiev and Petko Kovatchev</i>	552
Data Transfer Model for HIS and Developers Opinions in Turkey <i>Filiz Isleyen and M. Mahir Ulgu</i>	557
Decision Quality Is a Preference-Sensitive Formative Concept: How Do Some Existing Measures Compare? <i>Jack Dowie and Mette Kjer Kaltoft</i>	562
Defining the Contextual Problem List <i>John Meredith, Ian McNicoll, Nik Whitehead and Kemi Ademoye</i>	567
Digital Follow-Up Application for Cancer Patients – Value Mechanisms Regarding Health Professionals' Work <i>Sauli Miettinen and Henni Tenhunen</i>	572
Digital Technology Trends Supporting Assisted Independent Living of Ageing Population <i>Anthony Maeder</i>	577
Electronic Health Records as a Facilitator for the Implementation of a Strategy for the Reduction of Maternal and Child Morbi-Mortality in Buenos Aires City <i>Ivan Recalde, Denise Levi, Mariano Franco, Santiago Esteban and Analía Baum</i>	582
Evaluating Quality of Electronic Clinical Notes Using the Spanish Version of Physician Documentation Quality Instrument (PDQI-9) in a High-Complexity Hospital. Cross-Sectional Study <i>Giuliana Colussi, Amalia Botto, Romina Giudicessi, Laura Gomel, Aldo Marangone, Miguel Rodriguez and Sonia Benitez</i>	587

Evaluation of openEHR Repositories Regarding Standard Compliance <i>Maximilian Fechner, Tobias J. Brix, Tobias Hardt, Johannes Oehm, Martin Dugas and Michael Storck</i>	592
Formal Modelling of FHIR Based, Medical Data Exchange Using Algebraic Petri Nets <i>Franziska Bathelt, Michèle Kümmel, Sven Helfer, Christian Kamann and Martin Sedlmayr</i>	597
Health Metrics Network (HMN-WHO), a Tool to Assess the Quality of the Information System in Burkina Hospitals <i>Seydou Golo Barro, Amadou Dicko, Paul-André De Lame and Pascal Staccini</i>	602
Implementation and Analysis of Two Knowledge Base Approaches for the Treatment of Chronic Wounds <i>Stefan Vogel, Jendrik Richter, Stefanie Wache, Kerstin Pischek-Koch, Simon Auchter, Sebastian Zebbities, Karen Güttler, Ursula Hübner, Mareike Pryzsucha, Jens Hüsters and Björn Sellemann</i>	607
Information Capturing in Pre-Hospital Emergency Medical Settings (EMS) <i>Kerstin Denecke, Lea Meier, Jan G. Bauer, Matthias Bender and Christopher Lueg</i>	613
Integrating Pharmacogenetic Decision Support into a Clinical Information System <i>Kevin Tippenhauer, Marwin Philips, Carlo R. Largiadèr, Murat Sariyar and Thomas Bürkle</i>	618
Localisation, Personalisation and Delivery of Best Practice Guidelines on an Integrated Care and Cure Cloud Architecture: The C3-Cloud Approach to Managing Multimorbidity <i>George Despotou, Gokce B. Laleci Erturkmen, Mustafa Yuksel, Bunyamin Sarigul, Pontus Lindman, Marie-Christine Jaulent, Jacques Bouaud, Lamine Traore, Sarah N. Lim Choi Keung, Esteban De Manuel, Dolores Verdoy, Antonio De Blas, Nicolas Gonzalez, Mikael Lilja, Marie Sherman, Malte Von Tottleben, Marie Beach, Christopher Marguerie, Liran Karni, Gunnar O. Klein, Dipak Kalra, Rong Chen and Theodoros N. Arvanitis</i>	623
Making a Subjective Notion Computer-Interpretable: The Case of the Tumour-Volume to Breast-Volume Ratio for the Surgical Decision of Breast Cancer <i>Claudia Blancafort, Jacques Bouaud, Coralie Prebet and Brigitte Seroussi</i>	628
More Information Continuity Through Health Networks? Barriers to Implementation and Use of Health IT <i>Özlem Teckert</i>	633
Nursing Record Innovations Aimed at Harmonizing Structured Clinical Knowledge Among Doctors and Nurses <i>Satoko Tsuru, Tetsuro Tamamoto, Hitoshi Furuya, Akihiro Nakao, Mari Fukuyama, Kouichi Tanizaki and Naohisa Yahagi</i>	638

Physicians' Experiences of Patient-Initiated Online Consultations in Primary Care Using Direct-To-Consumer Technology <i>Sabine Koch and Miwa Guhres</i>	643
PM-TOM: A Method for Finding Personalized Polypharmacy Therapies with Minimal Adverse Drug-Drug, Drug-Gene and Drug-Condition Interactions <i>Adnan Kulenovic and Azra Lagumdzija-Kulenovic</i>	648
Practical Implementation of Receiver-Oriented Encryption in STROKE OWL <i>Timo Michelsen, Christian Lins, Andreas Hein and Christian Lüpkes</i>	653
Relationship Between Exercise Duration in Multimodal Telerehabilitation and Quality of Sleep in Patients with Multiple Sclerosis <i>In cheol Jeong, Herbert Karpatkin, Joel Stein and Joseph Finkelstein</i>	658
Role-Based Architecture for Secure Management of Telepathology Sessions <i>Rui Jesus, Pedro Nunes, Rui Lebre and Carlos Costa</i>	663
Safer Surgery Checklist: Barriers in the Adoption of Tablets in Operating Room <i>Giuliana Colussi, Gabriela Garcia, Maria Grande and Daniel Luna</i>	668
Sensor-Based Decision Support for the Allocation of Patient Attendants in Hospitals <i>Sascha Gfeller, Philip Kyburz, Kai-Uwe Schmitt, Thomas Bürkle, Jürgen Holm and Murat Sariyar</i>	673
Smart Ageing: Digital Solutions for Future Care <i>Anthony Maeder and Gary Morgan</i>	678
Statistically Prioritized and Contextualized Clinical Decision Support Systems, the Future of Adverse Drug Events Prevention? <i>Emmanuel Chazard, Jean-Baptiste Beuscart, Michaël Rochoy, Olivia Dalleur, Bertrand Decaudin, Pascal Odou and Grégoire Fichet</i>	683
Tackling Polypharmacy: A Multi-Source Decision Support System <i>Guilherme Redeker and Juliana Bowles</i>	688
The House of Carbs: Personalized Carbohydrate Dispenser for People with Diabetes <i>Pietro Randine, Daniela Micucci, Gunnar Hartvigsen and Eirik Årsand</i>	693
Update on the DMP, the French Nationally Shared Medical Record: Did We Make It? <i>Brigitte Séroussi and Jacques Bouaud</i>	698
User Requirements Meet Large-Scale EHR Suites: Norwegian Preparations for Epic <i>Gunnar Ellingsen and Morten Hertzum</i>	703
Value Mechanisms in the Implementation of Intelligent Patient Flow Management System – A Multiple Case Study <i>Tuomo Tanila, Henni Tenhunen and Petteri Hirvonen</i>	708
Virtual Reality Therapy for Social Phobia: A Scoping Review <i>Elham Salehi, Mahdi Mehrabi, Farhad Fatehi and Asiyeh Salehi</i>	713

Visualizing the Cascade Effect of Redesigning Features in an EMR System <i>Samar Helou, Victoria Abou-Khalil, Goshiro Yamamoto, Osamu Sugiyama and Tomohiro Kuroda</i>	718
Web Application for Home Care Providers <i>Virginia Sandulescu, Sorin Puscoci, Monica Petre, Alexandru Girlea and Viorel Bota</i>	723

Part 2

Section 3. Health and Prevention

A Model for Early Identification of Chronic Obstructive Pulmonary Disease <i>Thomas Kronborg, Stine Hangaard and Ole Hejlesen</i>	731
A Study of the Possibility of Detecting Pediatric Mild Developmental Delay Through a Serious Game: A Randomized Cluster Trial in Cambodia <i>Ho Heon Kim, Hong Wook Kwon, Sambath Kao, Hyuk-Sang Sohn, Joohye Kim, Yejin Choi, Doora Kim, Mirae Kang and Yu Rang Park</i>	736
Current Use of Sensor-Based Measurements for Paraplegics: A Literature Review <i>Nils-Hendrik Benning, Niclas Hagen and Petra Knaup</i>	741
Detection of Psychomotor Agitation Pattern from Motion Sensor Data in a Living Environment of a Patient with Dementia <i>Corinna Mielke, Rasmus Antons and Reinhold Haux</i>	746
ECG-Quality Assessment of Dry-Electrode Cooperative Sensors <i>Michael Rapin, Josias Wacker, Damien Ferrario, Etienne Haenni, Stephan Dasen and Olivier Chéhelat</i>	751
Gesture Classification for a Hand Controller Device Using Neural Networks <i>Stelian Nicola, Oana Sorina Chirila and Lacramioara Stoicu-Tivadar</i>	756
Natural Language Processing for Detecting Medication-Related Notes in Heart Failure Telehealth Patients <i>Alphons Eggerth, Karl Kreiner, Dieter Hayn, Bernhard Pfeifer, Gerhard Pölzl, Tim Egelseer-Bründl and Günter Schreier</i>	761
Patient-Generated Health Data in the Clinic <i>Nirusha Jeevanandan and Christian Nøhr</i>	766
Register-Based Research of Adverse Events Revealing Incomplete Records Threatening Patient Safety <i>Ulla-Mari Kinnunen, Eija Kivekäs, Sari Palojoiki and Kaija Saranto</i>	771
Teletriage Pilot Study (Strategy for Unscheduled Teleconsultations): Results, Patient Acceptance and Satisfaction <i>Andrés Santiago Frid, María Florencia Grande Ratti, Ana Pedretti, Marina Valinoti, Bernardo Martínez, Janine Sommer, Daniel Luna and Fernando Plazzotta</i>	776

The Renal Health Instagram: An Analysis of Comments <i>Geraldo Bezerra da Silva Junior, Marjan Askari, Diovana Ximenes Cavalcante Dourado, Juliana Gomes Ramalho de Oliveira and José Eurico de Vasconcelos Filho</i>	781
Use of Social Media Apps by Nurses for Professional Purposes in Catalonia: Cross-Sectional Study <i>Antonio Torrejon, Octavi Rodriguez-Blanco and Miguel A. Mayer</i>	786
Visual Representation of African Traditional Medicine Recipes Using Icons and a Formal Ontology, ontoMEDTRAD <i>Appoh Kouame, Konan Marcellin Brou, Moussa Lo and Jean Baptiste Lamy</i>	791
What Do We Know About the Use of Chatbots for Public Health? <i>Elia Gabarron, Dillys Larbi, Kerstin Denecke and Eirik Årsand</i>	796
Section 4. Precision Medicine and Public Health	
A Stroll Along the Erroneous ePrescription Interactions Within the Belgian Pharmacy <i>Sven Van Laere, Ronald Buyl and Marc Nyssen</i>	803
A Structured Measurement of Highly Synchronous Real-Time Ballistocardiography Signal Data of Heart Failure Patients <i>Nico Jähne-Raden, Udo Bavendiek, Henrike Gütschleg, Ulf Kulau, Stephan Sigg, Marie Wolf, Tanja Zeppernick and Michael Marschollek</i>	808
Addressing the Search Challenges of Precision Medicine with Information Retrieval Systems and Physician Readers <i>Kate Fultz Hollis, Kirk Roberts, Steven Bedrick and William R. Hersh</i>	813
Argentinian Digital Health Strategy <i>Daniel A. Rizzato Lede, Federico A. Pedernera, Emiliano López, Cintia D. Speranza, Carlos Guevel, Jesse J. Maid, Patricia Mac Culloch, Floencia Rolandi, Fabiana Ayala, Daniel A. Abadie, María I. Baqué, Fernando Gassino, Fernando Campos, Diego Kaminker, Cintia A. Cejas, Alejandro López Osornio and Adolfo Rubinstein</i>	818
Assessing Opioid Use Patient Representations and Subtypes <i>Sarah Mullin and Peter Elkin</i>	823
Automated Engineering for Health Smart Homes: Find a Way in the Jungle of Assistance Systems <i>Bastian Wollschlaeger and Klaus Kabitzsch</i>	828
Decreasing Number of Medication Prescriptions After e-Prescriptions Became Mandatory and Their Valid Period Was Extended: A Big Bang Policy Change in Finland in 2017 <i>Vesa Jormanainen, Toni Relander, Vilma Jormanainen and Marina Lindgren</i>	833

Exploratory Analysis of HIV Status Knowledge and Associated Factors Using Data from Electronic Medical Records	838
<i>Natividad Burdisso, Santiago Esteban, Karin S. Kopitowski and Sergio A. Terrasa</i>	
Global Public Health Surveillance Using Media Reports: Redesigning GPHIN	843
<i>Dave Carter, Marta Stojanovic, Philip Hachey, Kevin Fournier, Simon Rodier, Yunli Wang and Berry De Bruijn</i>	
ICT Toolkit for Integrated Prevention, Testing and Linkage to Care Across HIV, Hepatitis, STIs and Tuberculosis in Europe	848
<i>Christine Kakalou, Lella Cosmaro, Vlasios K. Dimitriadis, Anne Raahauge, Dorthe Raben and Vassilis Koutkias</i>	
Improving Dengue Surveillance System with Administrative Claim Data in Indonesia: Opportunities and Challenges	853
<i>Atina Husnayain, Anis Fuad, Ida Safitri Laksono and Emily Chia-Yu Su</i>	
Intelligent Tools for Precision Public Health	858
<i>Anya Okhmatovskaia and David L. Buckeridge</i>	
Machine Learning-Based Identification of Obesity from Positive and Unlabelled Electronic Health Records	864
<i>Vicent Blanes-Selva, Salvador Tortajada, Ruth Vilar, Bernardo Valdivieso and Juan M. García-Gómez</i>	
Medical Informatics in the Digital Personalized Health and Medicine Era: A SWOT Analysis and Actionable Strategies	869
<i>Rada Hussein</i>	
Mining Potential Effects of HUMIRA in Twitter Posts Through Relational Similarity	874
<i>Keyuan Jiang, Shichao Feng, Liyuan Huang, Tingyu Chen and Gordon R. Bernard</i>	
Ontology-Guided Policy Information Extraction for Healthcare Fraud Detection	879
<i>Theodora S. Brisimi, Vanessa Lopez, Valentina Rho, Marco Sbodio, Gabriele Picco, Morten Kristiansen, John Segrave-Daly and Conor Cullen</i>	
Text-Mining Services of the Swiss Variant Interpretation Platform for Oncology	884
<i>Déborah Caucheteur, Julien Gobeill, Anaïs Mottaz, Emilie Pasche, Pierre-André Michel, Luc Mottin, Daniel J. Stekhoven, Valérie Barbié and Patrick Ruch</i>	
The Smart Device System for Movement Disorders: Preliminary Evaluation of Diagnostic Accuracy in a Prospective Study	889
<i>Julian Varghese, Michael Fajarski, Tim Hahn, Martin Dugas and Tobias Warnecke</i>	
User Expectations and Willingness to Share Self-Collected Health Data	894
<i>Ashenafi Zebene Woldaregay, André Henriksen, David-Zacharie Issom, Gerit Pfuhl, Keiichi Sato, Aude Richard, Christian Lovis, Eirik Årsand, Jessica Rochat and Gunnar Hartvigsen</i>	

Section 5. Human Factors and Citizen Centered Digital Health

A Path Towards Inclusion: Transdisciplinary Experience for the Inclusion of Self-Perceived Gender in an Information System	901
<i>Melanie Cassarino, Eunice Correa, Sebastián Minoletti, Amalia Botto, Romina Rapisarda, María Florencia Grande Ratti and Daniel Luna</i>	
A Systematic Review on CDSS Alert Appropriateness	906
<i>Olufisayo Olakotan, Maryati Mohd Yusof and Sharifa Ezat Wan Puteh</i>	
Analysing Sentiment and Topics Related to Multiple Sclerosis on Twitter	911
<i>Guido Giunti, Maëlick Claes, Enrique Dorronzoro Zubiete, Octavio Rivera-Romero and Elia Gabarron</i>	
Automatic Interpretation of Laboratory Tests and Its Influence on Follow-up	916
<i>Georgy Kopanitsa</i>	
Clinical-Based and Expert Selection of Terms Related to Depression for Twitter Streaming and Language Analysis	921
<i>Angela Leis, Miguel-Angel Mayer, Francesco Ronzano, Marta Torrens, Claudio Castillo, Laura I. Furlong and Ferran Sanz</i>	
Design of the CAPABLE Health Empowerment Tool: Citizens' Needs and Expectations	926
<i>Astri Letnes Janson, Anne Moen and Kristin Skeide Fuglerud</i>	
Designing a Patient-Centered Notification System into a PHR	931
<i>Mariana Simón, Giuliana Colussi, Janine Sommer, Lucila Bruchanski and Fernando Plazzotta</i>	
Developing an Intervention to Implement Electronic Patient-Reported Outcomes in Renal Services in the UK	936
<i>Sabine N. Van Der Veer, Angelo Ercia, Fergus J. Caskey, Ken Farrington, Francine Jury, Michael Rees, Tim Whitlock and Sarah Knowles</i>	
Development of a ePRO-Based Palliative Care Intervention for Cancer Patients: A Participatory Design Approach	941
<i>Christina Karamanidou, Christos Maramis, Kostas Stamatopoulos and Vassilis Koutkias</i>	
Development of a Mobile Digital Manikin to Measure Pain Location and Intensity	946
<i>Sabine N. Van Der Veer, Anna L. Beukenhorst, S. Mustafa Ali, Ben James, Pedro Silva, John McBeth and William G. Dixon</i>	
Digital Support for Self-Management in Children with Diabetes: Understanding Their Needs and Developing a Design Concept	951
<i>Nicole Safavi Andersen, Louise Hedrich Haugaard, Sissel Bøgh Pedersen, Mikkel Strange Pedersen and Ann Bygholm</i>	
Does Health-IT Improve People Centered Care?	956
<i>Pernille Bertelsen, Lone Stub Petersen and Christian Nøhr</i>	

eSource-Enabled vs. Traditional Clinical Trial Data Collection Methods: A Site-Level Economic Analysis <i>Eric L. Eisenstein, Maryam Y. Garza, Mitra Rocca, Gideon S. Gordon and Meredith Zozus</i>	961
Health Professionals' Experiences of the Benefits and Challenges of Online Symptom Checkers <i>Sari Kujala, Iris Hörhammer, Riitta Hänninen-Ervasti and Tarja Heponiemi</i>	966
How Come Nothing Changed? Reflections on the Fasting-Time Project <i>Morten Hertzum and Jesper Simonsen</i>	971
How to Evaluate Health Applications with Conversational User Interface? <i>Kerstin Denecke and Jim Warren</i>	976
Implementation of an Open-Source Electronic Health Record for Decision-Support Education in Medical Informatics <i>Stephanie Medlock, Roland Schermer and Ronald Cornet</i>	981
Implementation of EXABO – An Expert Advisory Board for the European Reference Network for Rare Respiratory Diseases <i>Désirée Walther, Olivia Steinmann, Thomas O.F. Wagner and Holger Storf</i>	986
Integrating a Secure and Generic Mobile App for Patient Reported Outcome Acquisition into an EHR Infrastructure Based on FHIR Resources <i>Nico Ploner and Hans-Ulrich Prokosch</i>	991
Interaction with Medical Venues in Megacities <i>Maria Óskarsdóttir and Anna Sigríður Íslind</i>	996
Investigating the Barriers to Physician Adoption of an Artificial Intelligence-Based Decision Support System in Emergency Care: An Interpretative Qualitative Study <i>Cécile Petitgand, Aude Motulsky, Jean-Louis Denis and Catherine Régis</i>	1001
Learning Interpretable Behavioral Engagement for Care Management <i>Subhro Das, Chandramouli Maduri, Ching-Hua Chen and Pei-Yun S. Hsueh</i>	1006
<i>Mi Argentina/Mi Salud</i> : The Argentinian Citizen Digital Health Portal <i>Daniel A. Rizzato Lede, Federico A. Pedernera, Emiliano López, Cintia D. Speranza, Jesse J. Maid, Fernando Gassino, Osvaldo Argibay, Rodrigo Castiglione, Guillermo Pujadas, Emanuel Gonzalez Alvaredo, Rodrigo Álvarez, Maria B. Markiewicz, Florencia Alegre, Leandro Ferrareis, Florencia Rolandi, Fabiana Ayala, Daniel A. Abadie, Cintia A. Cejas, Alejandro López Osornio and Adolfo Rubinstein</i>	1011
Nutrikids, a Smartphone Application to Improve the Quality of Paediatric Dietary Assessments: Feasibility Study <i>Léa Jacques, Catherine Bussien, Camille Descloux, Lisa Decorsaire, Christian Lovis and Frédéric Ehrler</i>	1016

On Patient Accessible Electronic Health Records and the Experienced Effect on the Work Environment of Nurses <i>Jonas Moll and Åsa Cajander</i>	1021
Online Medication Information for Citizens: A Comparison of Demands on eHealth Literacy <i>Helen Monkman, Thomas Schmidt and Christian Nøhr</i>	1026
Personalized Communication – People with Hearing Loss’ Experiences of Using a National Patient Portal <i>Maria Hägglund, Emma Helsing and Isabella Scandurra</i>	1031
Process Approach for Managing Health Information System-Induced Medication Errors <i>Maryati Mohd. Yusof, Toshihiro Takeda, Naoki Mihara and Yasushi Matsumura</i>	1036
Qualitative Evaluations of mHealth Interventions: Current Gaps and Future Directions <i>Meghan Bradway, Kari Leibowitz, Kathleen A. Garrison, Lauren Howe and Eirik Årsand</i>	1041
Social Robots for Elderly Care: An Inventory of Promising Use Cases and Business Models <i>Somaya Ben Allouch and Lex van Velsen</i>	1046
The Digital Transformation of Patient-Reported Outcomes’ (PROs) Functionality Within Healthcare <i>Jepe Eriksen, Pernille Bertelsen and Ann Bygholm</i>	1051
The Effect of Patient Accessible Electronic Health Records on Communication and Involvement in Care – A National Patient Survey in Sweden <i>Jonas Moll and Hanife Rexhepi</i>	1056
The Patient as Genomic Data Manager – Evaluation of the PROMISE App <i>Lena Griebel, Marc Hinderer, Ali Amr, Benjamin Meder, Marc Schweig, Dominic Deuber, Christoph Egger, Claudia Kawohl, Annika Krämer, Isabell Flade, Dominique Schröder and Hans-Ulrich Prokosch</i>	1061
Towards a Highly Usable, Mobile Electronic Platform for Patient Recruitment and Consent Management <i>Daniel Robins, Rachel Brody, In Cheol Jeong, Irena Parvanova, Jiazhen Liu and Joseph Finkelstein</i>	1066
Towards a Lean Process for Patient Journey Mapping – A Case Study in a Large Academic Setting <i>Marieke Sijm-Eeken, Jaqueline Zheng and Linda Peute</i>	1071
User Experience Theories, Models, and Frameworks: A Focused Review of the Healthcare Literature <i>Blake Lesselroth, Helen Monkman, Kathleen Adams, Scott Wood, Audrey Corbett, Juell Homco, Elizabeth M. Borycki, Ross Spier and Andre W. Kushniruk</i>	1076

User-Centred Approach to Design an Online Social Support Platform for Seniors: Identification of Users' Types and Their Requirements	1081
<i>Arnaud Ricci, Jessica Rochat, Henk Herman Nap, Lotte Cornelisse, Christian Lovis and Frédéric Ehrler</i>	

Section 6. Ethics, Legal and Societal Aspects

Autonomous Systems and Artificial Intelligence in Healthcare Transformation to 5P Medicine – Ethical Challenges	1089
<i>Bernd Blobel, Pekka Ruotsalainen, Mathias Brochhausen, Frank Oemig and Gustavo A. Uribe</i>	
Big Data, Information Technology and Information Professionals: Some Considerations for Digital Ethics	1094
<i>E-H. Kluge</i>	
Citizens' Participation in Health and Scientific Research in Switzerland	1098
<i>Jessica Rochat, Christophe Gaudet-Blavignac, Marzia Del Zotto, Victor Ruiz Garretas, Vasiliki Foufi, David Issom, Caroline Samer, Samia Hurst and Christian Lovis</i>	
Designing a Solution to Manage Electronic Consent for Children	1103
<i>Gary Leeming, Sarah Thew and John Ainsworth</i>	
Effectiveness of Web Accessibility Policy Implementation in Online Healthcare Information	1108
<i>Muzawir Arief, Sari Rissanen and Kaija Saranto</i>	
Evolution of Interdisciplinarity in Medical Informatics in Europe: Patterns from Intertwining Histories	1113
<i>Casimir A. Kulikowski and George I. Mihalas</i>	
General Data Protection Regulation (GDPR) in Healthcare: Hot Topics and Research Fronts	1118
<i>Farhad Fatehi, Farkhondeh Hassandoust, Ryan K.L. Ko and Saeed Akhlaghpour</i>	
Health 'Big Data' Value, Benefit, and Control: The Patient eHealth Equity Gap	1123
<i>Paul Demuro, Carolyn Petersen and Paul Turner</i>	
Human-Induced Errors in Networked Healthcare Research: Risk Management Under the GDPR	1128
<i>Jonas Bienenzeisler, Hauke Fischer, Volker S. Thiemann and Rainer Röhrig</i>	
Impact Analysis of the Policy for Access of Administrative Data in France: A Before-After Study	1133
<i>Vincent Looten and Marie Simon</i>	
Legal and Ethical Issues in Secondary Use of Administrative Health Data: The Case of Latvian Healthcare Monitoring Datalink	1138
<i>Signe Mezinska, Arnis Buka, Agnese Bankava and Juris Barzdins</i>	

The Definition of Informatics Competencies in Finnish Healthcare and Social Welfare Education	1143
<i>Alpo Värri, Minna Tiainen, Elina Rajalahti, Ulla-Mari Kinnunen, Lea Saarni and Outi Ahonen</i>	

Section 7. Swiss Personalized Health Network

SPHN – Development and Usability Testing of an Electronic General Consent Prototype	1151
<i>Julia Maurer, Ramon Saccilotto, Jörg Willers, Pascal Düblin, Vu Duong and Christiane Pauli-Magnus</i>	
SPHN – The Swiss Personalized Health Network Initiative	1156
<i>Adrien K. Lawrence, Liselotte Selter and Urs Frey</i>	
SPHN/PHRT – MedCo in Action: Empowering the Swiss Molecular Tumor Board with Privacy-Preserving and Real-Time Patient Discovery	1161
<i>Jean Louis Raisaro, Juan Ramón Troncoso-Pastoriza, Sylvain Pradervand, Michel Cuendet, Mickael Misbach, Joao Sa, Francesco Marino, Nicolas Freundler, Nicolas Rosat, David Cavin, Alexander Leichtle, Jacques Fellay, Olivier Michielin and Jean-Pierre Hubaux</i>	
SPHN/PHRT: Forming a Swiss-Wide Infrastructure for Data-Driven Sepsis Research	1163
<i>Adrian Egli, Manuel Battegay, Andrea C. Büchler, Peter Bühlmann, Thierry Calandra, Philippe Eckert, Hansjakob Furrer, Gilbert Greub, Stephan M. Jakob, Laurent Kaiser, Stephen L. Leib, Stephan Marsch, Nicolai Meinshausen, Jean-Luc Pagani, Jerome Pugin, Gunnar Rättsch, Jacques Schrenzel, Reto Schüpbach, Martin Siegemund, Nicola Zamboni, Reinhard Zbinden, Annelies Zinkernagel and Karsten Borgwardt</i>	
SPHN – The Swiss Aging Citizen Reference (SACR)	1168
<i>Ayoung Jeong, Murielle Bochud, Philippe Cattin, Manolis Dermitzakis, Bogdan Draganski, Andreas Papassotiropoulos, Martine Preisig, Bram Stieltjes, Peter Vollenweider and Nicole Probst-Hensch</i>	
SPHN – The BioMedIT Network: A Secure IT Platform for Research with Sensitive Human Data	1170
<i>Diana Coman Schmid, Katrin Crameri, Sabine Oesterle, Bernd Rinn, Thierry Sengstag, Heinz Stockinger, on behalf of the BioMedIT network team: Leila T. Alexander, Jonathan Barda, Christian Bolliger, Urban Borstnik, Gerhard Bräunlich, Olivier Byrde, Jérôme Dauvillier, Robin Engler, Pablo Escobar Lopez, Volker Flegel, Martin Fox, Sofia Georgakopoulou, Jani Heikkinen, Martin Jacquot, Nicolas Kowenski, Guillermo Losilla, Sergio Maffioletti, Jorge Molina, Diego Moreno, Allen Neeser, Michal Okoniewski, Warren Paulus, Kevin Sayers, Torsten Schwede, Jaroslaw Surkont, Richard Wartenburger and Thomas Wüst</i>	

Section 8. Posters

- A Digital Service Logistics Information System for Emergency Department
Care Coordination – Professionals’ Experiences 1177
*Laura-Maria Peltonen, Armi Kuloheimo, Kristiina Junttila
and Sanna Salanterä*
- A Matlab Tool for Organizing and Analyzing NHANES Data 1179
*Simon Lebech Cichosz, Morten Hasselstrøm Jensen,
Thomas Kronborg Larsen and Ole Hejlesen*
- A Path to Inclusion: Design and Prototype of Transgender Identity
in an Electronic Health Record 1181
*Melanie Cassarino, Eunice Correa, Sebastián Minoletti, Ignacio Jauregui,
Maria Florencia Grande Ratti, Carlos Otero and Daniel Luna*
- A Recommender System Based on Cohorts’ Similarity 1183
*João Rafael Almeida, Eriksson Monteiro, Luís Bastião Silva,
Alejandro Pazos and José Luís Oliveira*
- A Smart Mapping Editor for Standardised Data Transformation 1185
*Hannes Ulrich, Sebastian Germer, Ann-Kristin Kock-Schoppenhauer,
Jori Kern, Martin Lablans and Josef Ingenerf*
- Accessible Rates to Health Information on the Internet in Elderlies Increased
Among Fifteen Years 1187
Takeo Shibata, Akemi Kunitatsu, Chika Hiraga and Yoko Shimizu
- Addressing Ethics in the CrowdHEALTH RDI Project Concerned with Large
Amounts of Data to Support Health Policies 1189
Lydia Montandon
- Advanced Machine Learning in Prediction of Second Primary Cancer
in Colorectal Cancer 1191
Chi-Chang Chang and Ying-Chen Chen
- Agent-Based Modeling and Simulation of Care Delivery for Patients
with Thrombotic and Bleeding Disorders 1193
*Noemi Giordano, Samanta Rosati, Federica Valeri,
Alessandra Borchellini and Gabriella Balestra*
- An “in silico” Bench to Bedside Approach to Investigating Sepsis Biomarkers 1195
*Grace O’Mahony, Christopher Hawthorne, Karl McQuaid
and Guillermo H. Lopez-Campos*
- An Online Prevention Tool for Ophthalmological Disorders 1197
Maria Patte, Joseph Liaskos, Paris Gallos and John Mantas
- Analysis of Professional Competencies for the Clinical Research Data
Management Profession 1199
*Saly Abouelenein, Tremaine Williams, Jaime Baldner
and Meredith Nahm Zozus*

Application of IBM Watson to Support Literature Reviews: A Preliminary Experience in Restorative Dentistry	1201
<i>Giacomo Derchi, Marco Visentin, Vincenzo Marchio, Lisa Lardani, Antonio Barone, Marco Prenassi and Sara Marceglia</i>	
The Impact of Information Quality on Retracted Bioinformatics Literature	1203
<i>Austin Springer, Donna Chachere, Awaad Alsarkhi and Meredith Zozus</i>	
Association of C>U RNA Editing with Human Disease Variants	1205
<i>Sapan Mandloi, Zackary Falls, Rong Deng, Ram Samudrala and Peter L. Elkin</i>	
Automated Analysis of the Heterogeneity of Histological Glioblastoma Slides Using Neural Networks	1207
<i>Michael Oertl, Georg Prokop, Felix Holl, Marina Fotteler, Viktoria Muehlbauer, Walter Swoboda and Friederike Liesche-Starnecker</i>	
Automated Nerve Fibres Identification and Morphometry Analysis with Neural Network Based Tool in MATLAB	1209
<i>Michał Kopka, Wiktor Paskal, Adriana M. Paskal, Piotr Pietruski, Ryszard Kopka and Paweł K. Włodarski</i>	
Automatic Detection of Vital Signs in Clinical Notes of the Outpatient Settings	1211
<i>Martín Díaz Maffini, Fernanda Aguirre Ojea and Matías Manzotti</i>	
Best Practices for Designing Discrete Choice Experiments and the Use for Older Adults with Cognitive Impairment	1213
<i>Thomas Engelsma, Monique W.M. Jaspers and Anne M. Turner</i>	
Biostatistics Disruptive Acculturation Through Serious Gaming: A New Hope	1215
<i>Pierre Gillois, Lionel Di Marco, Josep M. Nicolàs, Alexandre Moreau-Gaudry, Anne Ego, Sandra David-Tchouda, Donald K. Martin and Jean-Luc Bosson</i>	
Challenges of In-House Development and Implementation of a CPOE for Oncology	1217
<i>S. de Matos Lima, C.L. Gimenez and D. Luna</i>	
Classification of Biceps Brachii Muscle Fatigue Condition Using Phase Space Network Features	1219
<i>Navaneethakrishna Makaram and Ramakrishnan Swaminathan</i>	
Classification of First-Episode Schizophrenia Using Wavelet Imaging Features	1221
<i>Kateřina Maršálová, Daniel Schwarz and Ivo Provazník</i>	
Classification of Histologic Images Using a Single Staining: Experiments with Deep Learning on Deconvolved Images	1223
<i>Vincenzo Della Mea and David Pilutti</i>	
Classification of Normal and Cardiomegaly Conditions in Chest Radiographs Using Cardio-Mediastinal Features	1225
<i>Satyavrat Govindarajan, Sukanta Kumar Tulo and Ramakrishnan Swaminathan</i>	

Classification of the Severity of Adverse Drugs Reactions <i>Raphaël Chauvet, Cédric Bousquet, Agnès Lillo-Lelouet, Ilan Zana, Ilan Ben Kimoun and Marie-Christine Jaulent</i>	1227
Coping with IT Downtime in Hospitals <i>Jackline Bamdeg and Thomas Schmidt</i>	1229
Creating and Implementing a Professional Development Program to Improve Organizational Capacity for Health Analytics in a Public Health Setting <i>Mariano Aizpurua, Tomás Galluzzi and Santiago Esteban</i>	1231
Cross-Mapping Study of Nursing Practice Terms from a Brazilian Hospital Database <i>Luciana Schleder Gonçalves, Dayane Andreatta and Fernanda Karoline Schamne</i>	1233
Data Integration Approaches for Representing Stem Cell Studies <i>Irena Parvanova and Joseph Finkelstein</i>	1235

Abstract. Research projects with humans is a highly regulated field that is currently undergoing rapid changes due to developments in eHealth and mHealth. While a patients data and samples must be thoroughly protected, they are also an invaluable source for fundamental and cutting edge research. There are processes in place to obtain a patient's consent for the use of their data and samples for research. These approaches could be more flexible, user-friendly and modernised. There is a high demand among all parties for a unified, yet differentiated, dynamic and personalised eConsent. An Android app has been developed that brings any existing consent form to mobile devices, including the integration of the process into existing hospital IT using established data standards, such as FHIR and the ResearchStack open source framework. The app is user-tested and shown to work in a hospital setting. Lack of identification and legal drawbacks were determined as the main obstacles for immediate implementation.

Keywords. eConsent, FHIR, Android, ResearchStack, digital hospital, eHealth

1. Introduction

Research projects with humans is a complex and highly regulated field [1], evolved through insight gained by trial and error over the recent decades. This research is subject to new challenges, where large collections of health data and biological samples stored in biobanks and databases, come in conflict with current ethical, legal, and societal implications. The number and size of these repositories is set to increase significantly over the coming years [2].

In Switzerland, the Human Research Act (HRA) [1] allows the use of these data and samples when consent by the patient is present. Consent may be given in form of the traditional *informed consent* (IC), tailored to a specific project, or *general consent* (GC), in which patients allow the use of their data and samples for future, previously unspecified research projects. The HRA as well as the data protection laws give strict instruction on how to handle these highly sensitive medical data and samples.

¹Corresponding Author: Manuela Weber; E-mail: manuela.weber@uzh.ch.

Recent developments in eHealth and mHealth research applications show demand for a consent system, attainable on a patient's own device (eConsent)[3], which may prove profitable to both patient and institution. An eConsent process can simplify a hospital's consent process, as well as allow patients to consent and withdraw at any time; define the terms and conditions for projects using their data and samples (*dynamic consent*); and help patients investigate projects their data and samples are being used in. Simplified hospital processes and increased patient autonomy are not the only benefits of eConsent; Consent forms are often very complex and riddled with medical or legal jargon, which may be better explained through explanatory images and videos. Electronic consent processes can inform patients sufficiently about research studies [4], as interactive elements of eConsent lead to better understanding and recall of key information [5,6]. Additionally, Switzerland is a multi-cultural country with four native languages, this excluding many other languages present due to migration. There is a dire need for quick, accessible and up-to-date consent forms in different languages.

The eConsent concept is not without its challenges. It is well known that older patients visit the hospital more frequently and make out a large sub-population who may have difficulties navigating the application. Furthermore, it may be seen that the eConsent is treated less seriously than a paper-based consent, even though both are legally binding. Nevertheless, current developments in the health system demand for more dynamic, differentiated, and personalised consent solutions.

The prototypes used in the various studies were rather pragmatic and isolated solutions [7] and when authors mentioned the chosen platform, it was mostly iOS based [5,6,8]. This may be due to Apple's initial lead in providing programming tools for the health sector i.e. ResearchKit (<http://researchkit.org>). Android developers, however, caught up by releasing ResearchStack (<http://researchstack.org>). There are now established data standards like FHIR (<https://www.hl7.org/fhir>) and open source frameworks available to create a unified eConsent process for different needs on both platforms, such as C3-PRO (<https://github.com/C3-PRO>).

In this context, the goal of this paper is the research and development of an eConsent technology available on Android and exploring the user acceptance in different patient populations. To our knowledge, we are one of the first team of researchers not only equipped with a prototype, but an eConsent app user tested and readily applicable. The project focus is technological feasibility, user acceptance, and reusability of existing paper consent forms. Our work concentrates on a simple design which allows novice programmers to set up eConsent processes for any paper-based consent form.

2. Methods

Our research consists of two main parts: the design of an easily constructed app and the evaluation of the app's acceptance amongst patients.

In the first step, we conducted a literature search of previous attempts and experiences with eConsent (PubMed, Google Scholar), deciding on the implementation environment. We chose the platform for the app and determined existing frameworks to make the implementation as easy and versatile as possible. The app was then developed, incorporating feedback from different stakeholders, such as thorough research into the technical and legal possibilities and challenges of connecting it to the existing IT environment of the hospital.

For the user acceptance evaluation, the consent forms for the collection of data and samples was integrated into the app and evaluated with patients of the dermatology and the visceral and transplant surgery department. So far, 52 patients were asked to participate of which 33 patients agreed. Patients of different ages were included whether or not they had previously signed the paper-based form.

The administrator selected the document on the eConsent app, scanned the patient label or filled in the patient data manually. The administrator gave a brief standardised introduction and handed the tablet to the patient. The patient read through the document by clicking through the frames, followed by their consent or refusal. When refusing, the process ended and returned to the home screen, while consenting led to a frame where patients signed on screen with a stylus pen. After signing and clicking "next", they returned the tablet to the administrator. In the last step, patients filled out a user acceptance evaluation questionnaire consisting of 9 questions concerning their age group, comprehension, user friendliness, readability, signature, font size, amount of content per frame, preference for eConsent or paper consent as well as general comments and overall experience. Due to current legal restrictions, a paper-based consent form always accompanied the electronic version.

3. Results

3.1. Implementation

With over 80% of mobile devices running worldwide on Android [9] with no restrictive licensing requirements, Android was our operating system of choice. The eConsent app was programmed in Android Studio using Java code. ResearchStack for Android offered an easy to use open source framework for implementation of research apps, including a user interface for a consent process that allows the signing of a consent document on the screen of mobile devices. Integration of the app into existing clinical IT infrastructure was made possible by C3-PRO, an open source toolchain to connect ResearchStack apps to clinical research IT infrastructure through the established standard for medical data FHIR [10].

The consent document, structured into subsections defined and provided by the ResearchStack, is stored in a json file as a FHIR contract resource. Among others, it provides sections for introductions, study information, privacy, usage of collected data and information on withdrawal of consent. Each section is displayed on screen for the patient to read and scroll through. Every section can show a "learn more" link, which navigates the patient to a different screen for more information. The json file containing the consent document is loaded into the app using the C3-PRO framework and passed on to the ResearchStack framework to be presented to the user. To start the consent process, a custom label reader was implemented to read a standard patient bar code and retrieve patient data needed for the consent document, such as name, date of birth and patient ID. The patient is then guided through the sections of the consent document and asked to agree to the terms by signing his signature on the screen of the device. After signing, a PDF of the consent form, complete with the patient information and signature is created and transmitted to the hospital IT system by the C3-PRO framework, either as a FHIR resource or as plain PDF.

3.2. User Acceptance Evaluation

The designed app can be set up for different consent forms with minimal effort. It can run on different Android devices and adjusts to different screen sizes. For the user acceptance study, the app was installed on a 10.5” Samsung tablet. From all 33 patients who completed the consent process and questionnaire, the app was generally positively received and found easy to navigate. The eConsent was generally determined superior over the paper-based version. Results of the questionnaire can be seen in Table 1. A few issues arose during the eConsent process. In some cases, the navigation buttons for the app were not big enough, the amount of text per section was too much and some patients expressed the need for a bigger signature area. Some users also experienced difficulties when resting the palm on the screen when signing. Over all, patients reflected positively about their experience with a few minor and adaptable issues.

Table 1. User Acceptance Questionnaire Results (n=33)

characteristic	comprehension	user friendliness	readability	signature
mean score*	4.6	4.2	4.2	3.2
improvement	integration of media, adjust text per frame	increase button size, swipe function	zoom function, larger font size	increase signature platform

*1 lowest score, 5 highest score

4. Discussion

This project creates a solution that allows a standardised eConsent process for various types of consents with minimal effort or programming knowledge. Due to the use of established data standards, the proposed app can easily be integrated into existing hospital IT infrastructures. The user acceptance evaluation has shown that patients of all ages navigated the technology easily and even prefer the digital version. If further requirements arise in the future, the technology offers plenty of options for adaptation and improvement.

Possible integration of different media types could allow for a more differentiated, dynamic and personalised experience for patients with different preferences. Numerous field tests show that there is wide acceptance and preference of eConsent among patients, medical professionals and researchers [4], which is corroborated by our results. Electronic forms instead of paper forms can lead to greater satisfaction for all parties [7] and field tests have shown that eConsent result in the same or higher consent rate [11,12].

Although the app is ready for implementation, there are some challenges concerning the integration of the app into the IT infrastructure of the institution. The main concern being legal and safety matters. Swiss law does not accept electronic hand-written signatures, with exception of the postal service. eSignatures such as Swiss Post’s SwissID can be costly, are not widely accepted, and do not easily integrate with third party software, such as ResearchStack. No Federal law on recognized eidentification is yet in force. Furthermore, data protection laws are very strict about patient data being stored on mobile devices and transmitted through potentially vulnerable networks. However, despite strict laws and best efforts, eHealth data has become more attractive to hackers over the recent years and are stored in less secure systems [13,14,15]. Substantial initial investment

would be necessary to establish a secure yet accessible infrastructure for a secure unified eConsent system.

5. Conclusion

It is time to supplement or replace paper-based consent forms with a unified yet dynamic and personalised eConsent process. The solution presented is accepted among patients and researchers, and easily integrated into existing and future health networks. The lack of options for eIdentification and legal drawbacks were determined as the main obstacle for immediate implementation.

Abstract. The cryptographic method *Secure Multi-Party Computation* (SMPC) could facilitate data sharing between health institutions by making it possible to perform analyses on a “virtual data pool”, providing an integrated view of data that is actually distributed – without any of the participants having to disclose their private data. One drawback of SMPC is that specific cryptographic protocols have to be developed for every type of analysis that is to be performed. Moreover, these protocols have to be optimized to provide acceptable execution times. As a first step towards a library of efficient implementations of common methods in health data sciences, we present a novel protocol for efficient time-to-event analysis. Our implementation utilizes a common technique called *garbled circuits* and was implemented using a widespread SMPC programming framework. We further describe optimizations that we have developed to reduce the execution times of our protocol. We experimentally evaluated our solution by computing Kaplan-Meier estimators over a vertically distributed dataset while measuring performance. By comparing the SMPC results with a conventional analysis on pooled data, we show that our approach is practical and scalable.

Keywords. secure multi-party computation; healthcare data; patient privacy; operational confidentiality of information

1. Introduction

The increasing abundance of digital health data holds great potential for medicine and healthcare. Paired with standardized data formats and analytic tools, this wealth of data can help to improve diagnosis, treatment and prevention as well as efficiency of care. However, health data is distributed across a large number of institutions, and the knowledge to be gained from these isolated data repositories is limited. This has led to the creation of a wide range of national and international data sharing initiatives. But laws and regulations such as the EU General Data Protection Regulation often prevent the disclosure and sharing of health data for privacy reasons.

Secure Multi-Party Computation (SMPC) is a cryptographic approach that can help to overcome this limitation and facilitate data sharing between health institutions. SMPC

¹ Corresponding Author, Lennart Vogelsang, Department of Computer Science, Humboldt-Universität zu Berlin, Rudower Chaussee 25, 12489 Berlin, Germany; E-mail: vogelsal@informatik.hu-berlin.de.

makes it possible to perform analyses on a *virtual data pool*, providing an integrated view of data that is actually distributed – without any of the participants having to disclose their private data [1].

Prior work on SMPC in healthcare includes a protocol for genome-wide association studies that keeps underlying geno- and phenotypes private [2], as well as a study that uses SMPC to investigate drug-target interactions in large pharmacological datasets [3]. Other applications include a disease surveillance system that ensures patient and provider privacy [4] and a method for privacy-preserving health record linkage [5].

2. Objective

Despite its potential as a privacy-preserving approach to health data sharing, SMPC is not yet widely used in health analytics. One reason for this is that SMPC is computationally demanding, and protocols therefore have to be highly optimized for acceptable performance.

As a first step towards a library of efficient SMPC implementations of common methods in health data sciences, we studied the problem of time-to-event analysis over vertically distributed data. In this scenario, one participant (e.g. a hospital) holds relevant clinical data (e.g. the primary diagnosis) while another participant (e.g. a medical practice or death register) holds data on relevant events (e.g. time of death or (re-)admission to hospital) of the same patient group. As a showcase, we present an efficient SMPC implementation of the Kaplan-Meier estimator for survival probabilities.

3. Methods

3.1. Secure Multi-Party Computation

Our implementation uses the Obliv-C framework [6], which provides an abstraction layer for the *garbled circuits* technique. With this widespread approach, two-parties can evaluate a common function without disclosing their inputs by mapping the function to a Boolean circuit [1]. Furthermore, we used a library providing additional primitives for sorting and secure memory that hides access patterns (ORAM) [7–9].

Figure 1. Example for the abstraction layer provided by Obliv-C.

Obliv-C provides an abstraction layer that imitates a Trusted Third Party (TTP). As illustrated in Figure 1, both parties A and B push their data a and b to the TTP, which calculates the function f and returns the output c . In reality, however, there is no TTP;

the computation and its inputs are encrypted and computations are executed distributively between both parties.

3.2. Efficient SMPC Protocol for Kaplan-Meier Estimators

One major drawback of SMPC is its computational overhead. To reduce this overhead, we split our problem into two phases: In the first, SMPC-based phase, computation is minimized and as much computation as possible is offloaded to the second, non-SMPC-based phase. As intermediate results from the SMPC program are revealed to the subsequent non-SMPC programs, special care has to be taken to make sure that these intermediate results do not leak private information.

In the particular case of the Kaplan-Meier estimator, the survival probabilities of individual patients should not be leaked, as this would create a direct mapping between the result and each patient's private information. Instead, values have to be aggregated so that only cumulated distinct data points are revealed. To aggregate time points in the SMPC phase, we used the secure memory (ORAM) mentioned above.

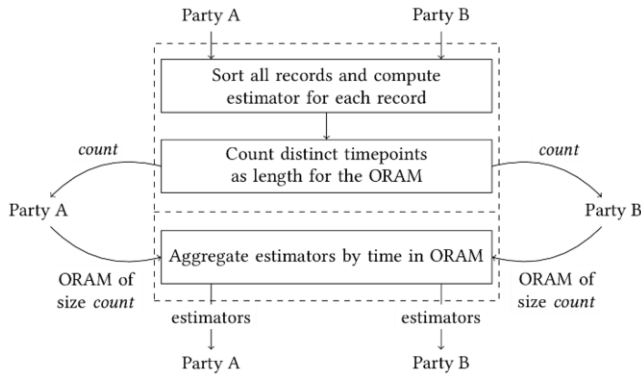

Figure 2. Schematic view of our algorithm implementing the Kaplan-Meier estimator.

One challenge with this approach is that the ORAM has to be initialized with a maximum size. While the number of patient records could be used as an upper bound, this adversely impacts performance, as ORAMs do not scale well. However, the length of the result is typically lower because time points get aggregated and not every patient has an event. The size of the ORAM can thus be limited to the number of distinct time points. We achieve this by iterating over the dataset in two (sub-) phases: first, we aggregate the values without storing them, only counting the number of distinct time points, revealing the count afterwards; then we initialize the ORAM and perform the calculations again, this time storing the results as shown in Figure 2. This does not impact privacy in any way, as the count is leaked at the end of the protocol anyway.

The source code of our SMPC protocol for Kaplan-Meier estimators is available at <https://github.com/LevitatingOrange/secure-kaplan-meier>.

3.3. Experimental Setup

In our experiments we used two datasets: (1) A synthetic dataset including patient demographics (date of birth, gender and postal code), case information (case number,

admission and discharge dates), coded diagnoses (ICD-10-GM) and procedures (German OPS codes); (2) a simulated dataset from a death registry. The datasets included a total of 3,927 patients with 5,110 cases. The patients shared a common identifier across both datasets (e.g. a social security or health insurance number).

We performed two experiments: (1) a “conventional” analysis in R (www.R-project.org) on the pooled datasets on one machine; (2) an analysis on distributed data with our SMPC protocol simulating two machines connected with a local area network (LAN, bandwidth: 119 Mbits/s, average latency: 0.347ms) and a wide area network (WAN, bandwidth: 31.3 Mbits/s, average latency: 5.11ms). We used two laptops for the LAN scenario: a six core Intel Core i7-8850H processor and 32 GB RAM machine and another with a four core Intel Core i7-4960HQ and 16 GB RAM. In the WAN scenario, we connected the former laptop to a virtual machine on a hosting provider with 12 GB RAM and a six core Intel Xeon E5-2680 processor.

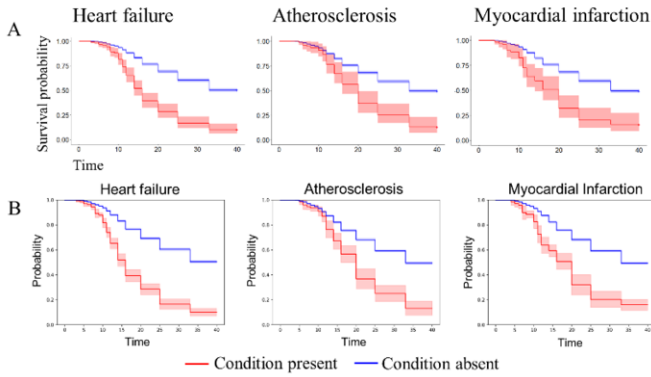

Figure 3. Kaplan-Meier plots obtained using (A) pooled data and (B) the SMPC protocol.

4. Results

Figure 3 shows the Kaplan-Meier graphs comparing patients with (vs. without) a diagnosis of heart failure (ICD-10 code: I50*), atherosclerosis (ICD-10 code: I70*) and myocardial infarction (ICD-10 code: I21*). As can be seen, the results obtained in both experiments were in high agreement.

Figure 4. Execution times of the SMPC Kaplan-Meier estimator in the LAN and WAN scenario.

Figure 4 shows the execution times of the SMPC protocol. Both scenarios (LAN and WAN) showed a linear increase in computation time in relation to the number of records processed. The complete dataset of nearly 4,000 records was processed in about five minutes in the WAN scenario.

5. Discussion and Conclusion

In this article, we have presented an efficient SMPC implementation of the Kaplan-Meier estimator over vertically distributed data.

Slight differences in the survival probabilities resulting from the SMPC and the conventional implementation can be explained by the fact that Obliv-C only supports 32-bit single precision floating point arithmetic (rather than the 64-bit precision floating-point operations of the conventional analysis). Moreover, the experiments showed that our approach provides practical execution times. Even with very large datasets (>1,000,000 records), we expect computations to take not more than several hours or maximally a few days. This is acceptable in typical research projects, especially when considering that the alternative, in many cases, would be not to do the project at all.

In future work, we plan to implement additional SMPC protocols for common statistical methods in health analytics and test them in real-world scenarios. An interesting candidate would be an SMPC implementation of a Cox proportional hazard model for more advanced statistical analyses of survival times. In the long-term, SMPC protocols could be made available in an open source library, providing a collection of methods that researchers can choose from for their specific projects.

For long, SMPC remained a largely academic field, especially due to its sub-par performance compared with traditional analysis methods. With recent progress towards efficient SMPC protocols and the focus on data privacy and security, SMPC can play a large role in advancing analysis across distributed healthcare data.

A Semantic Similarity Evaluation for Healthcare Ontologies Matching to HL7 FHIR Resources

Abstract. Healthcare 4.0 demands healthcare data to be shaped into a common standardized and interoperable format for achieving more efficient data exchange. Most of the techniques addressing this domain are dealing only with specific cases of data transformation through the translation of healthcare data into ontologies, which usually result in clinical misinterpretations. Currently, ontology alignment techniques are used to match different ontologies based on specific string and semantic similarity metrics, where very little systematic analysis has been performed on which semantic similarity techniques behave better. For that reason, in this paper we are investigating on finding the most efficient semantic similarity technique, based on an existing approach that can transform any healthcare dataset into HL7 FHIR, through the translation of the latter into ontologies, and their matching based on syntactic and semantic similarities.

Keywords. Healthcare, Ontology alignment, Semantic similarity, HL7 FHIR

1. Introduction

In the last decade, there has been a transition from a data-poor to a data-rich world, with the aim of improving the quality of transport, governance, environment, communication and health. Much of this unprecedented increase in data generation can be attributed to the abundance of thousands of mobile devices, wearables, and sensors. Most of these devices are typically characterized by a high degree of heterogeneity, in terms of having different characteristics, capabilities, or network specifications, needing to be easily manageable in particular with regard to the management of the heterogeneous data they generate. Especially for the Internet of Medical Things (IoMT) devices it is undeniable that vast amounts of heterogeneous medical data are becoming available, thus completely reshaping the Healthcare 4.0. In order for these heterogeneous medical data to be exchanged with multiple stakeholders, and to be a key driver of providing personalized and efficient medical care to patients and citizens, interoperability is the only way.

Taking into consideration these challenges, in [11] a holistic approach has been presented for achieving interoperability through the transformation of healthcare data into its corresponding HL7 FHIR structure. Shortly, the provided mechanism was building the healthcare ontologies that were stored into a triplestore, in order to identify

¹ Corresponding Author, Athanasios Kiourtis, 80, M. Karaoli & A. Dimitriou St., 18534 Piraeus, Greece
E-mail: kiourtis@unipi.gr.

and compare their syntactic and semantic similarity with the HL7 FHIR Resources. According to the aggregation of the syntactic and semantic similarity results, the alignment and translation to the HL7 FHIR was taking place. In this paper, we are going to fill the gap of the semantic similarity of the aforementioned mechanism, as there has been little systematic analysis on which semantic similarity techniques perform well when applied to ontology alignment.

The remainder of this paper is organized as follows. In Section 2, some semantic similarity techniques are illustrated, while Section 3 depicts the overall approach. Section 4 includes the evaluation of the derived results, presenting our concluding remarks.

2. Semantic Similarity Techniques

Several methods for determining semantic similarity between terms have been proposed in the literature. Word2Vec [2] is a two-level neural network that processes text. Its input is a body of text and its output is a set of vectors. The purpose and utility of Word2Vec is to group similar word vectors together in the vector space, detecting mathematical similarities. Word2Vec creates vectors that are distributed arithmetic word representations, such as the single word context, without human intervention. Given enough data, usage, and the current environment, Word2Vec can make very accurate guesses about the meaning of a word based on impressions of the current word in other situations in the past. WordNet [3] is a great English based dictionary. Nouns, verbs, adjectives, and adverbs are grouped into sets of synsets, each of which expresses a separate meaning. Synsets are interrelated through conceptual-semantic and lexical relationships. The resulting network of related words and concepts can be navigated with the browser. The structure of WordNet makes it a useful tool for computational linguistics and NLP. WordNet looks superficially like a treasure trove because it groups words according to their meanings. Cortical.io [4] proposes a new way of understanding the natural language that transcends the limitations of other artificial intelligence approaches. Semantic Folding [5] is inspired by the most recent findings on how the brain processes information. This theory introduces the Semantic Fingerprint, which explicitly codifies the concept, including all concepts and frameworks. The system understands the affinity of two elements by measuring the overlap of their fingerprints.

3. Proposed Approach

In the context of ontology alignment of healthcare data, several techniques are presented that lead to better decision making, and interoperable exchange and use of data, providing solutions that are adapted to deliver results under specific scenarios. To address this gap, in [1] a holistic approach is proposed that is capable of identifying common links between healthcare ontologies and the ontologies that represent the HL7 FHIR Resources. The preliminary steps of the developed approach were dealing with the automatic transformation of the healthcare dataset and the HL7 FHIR Resources into their ontological structure. As soon as the ontologies had been constructed, they were stored into a triplestore. Afterwards, two sub-mechanisms had occurred, providing the syntactic and the semantic similarity between two different ontologies, based on their syntactic representations and their semantic knowledge accordingly. The final stage of the mechanism implemented an additional sub-mechanism that aggregated and merged the

outcomes of the aforementioned sub-mechanisms, providing the overall alignment results, for the final transformation of the healthcare dataset into HL7 FHIR. Henceforth based on this developed mechanism, in our case, we assume that healthcare ontologies have already been constructed for both the ingested healthcare dataset and the different HL7 FHIR Resources. Consequently, the three described semantic similarity techniques are going to be implemented, for measuring the semantic similarity of the built ontologies.

3.1. Semantic Similarity Identifier

The objective of the Semantic Similarity Identifier is to provide the means for aligning and matching the different healthcare dataset and HL7 FHIR Resources ontologies, according to their semantic meaning (Fig. 1).

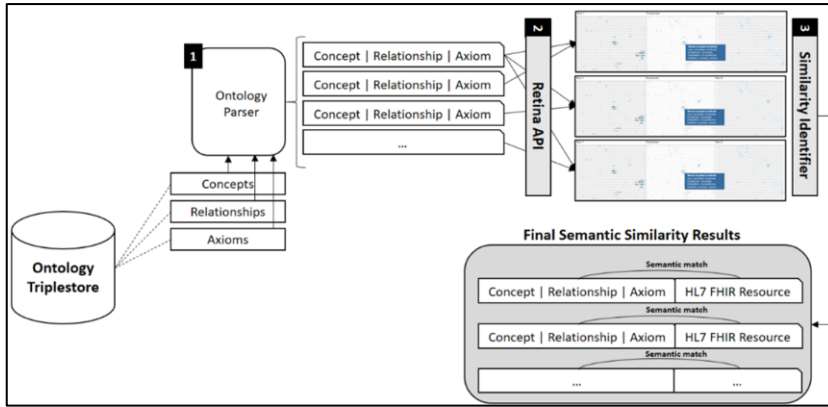

Figure 1. Semantic Similarity Identifier.

4. Evaluation

In our case, in order to evaluate the three different semantic similarity techniques, we are going to implement them under the same use case scenario where we will calculate their precision, recall, F-measure, and total errors [6], with respect to a UMLS-based reference alignment [7]. After this calculation, a comparison between the results will take place in order to conclude to the semantic similarity technique that is more suitable for aligning ontologies and calculating their semantic similarity in the healthcare domain.

4.1. Application of Semantic Similarity Techniques

The use case exploits a healthcare dataset structured in CSV format, covering all the previous steps, consisting of 5000 different instances of the personal information of certain citizens about their: (i) personal identifier (*subject*), (ii) gender (*gender*), (iii) date of birth (*dateOfBirth*), and (iv) cause of death (*causeOfDeath*). After performing the steps introduced into the Semantic Similarity Identifier, the following tables are being created (Table 1, Table 2, and Table 3), depicting the HL7 FHIR Resources with higher semantic similarity degrees, compared with the concept names of the use case dataset, through the three different semantic similarity techniques.

Table 1. Semantic Similarity Identifier Top Results for Cortical.io

Use Case Dataset Attribute	HL7 FHIR Resources	Cortical.io
subject	Patient.identifier	0.947 (~95%)
gender	Patient.gender	0.863 (~86%)
dateOfBirth	Patient.birthDate	0.971 (~97%)
causeOfDeath	Patient.deceased	0.458 (~46%)

Table 2. Semantic Similarity Identifier Top Results for Word2Vec

Use Case Dataset Attribute	HL7 FHIR Resources	Word2Vec
subject	Patient.contact.address	0.357 (~36%)
gender	Patient.gender	0.663 (~66%)
dateOfBirth	Patient.birthDate	0.891 (~89%)
causeOfDeath	-	0 (0%)

Table 3. Semantic Similarity Identifier Top Results for Wordnet

Use Case Dataset Attribute	HL7 FHIR Resources	Wordnet
subject	Patient.gender	0.772 (~77%)
gender	Patient.gender	0.861 (~86%)
dateOfBirth	Patient.multipleBirth	0.561 (~56%)
causeOfDeath	Patient. deceased	0.619 (~62%)

4.2. Conclusions & Discussion of Results

In order to evaluate these results with regards to the metrics of precision, recall, F-measure, and errors, the specific use case dataset was translated manually in HL7 FHIR, so as to compare the results of the developed mechanism, with the actual outcomes. In Fig. 2, a visualization of the aforementioned results is depicted through a bar chart, showing how the three different semantic similarity techniques behave in the total semantic similarity identification, with regards to the manually provided results which did not contain any errors (0% of errors), while their precision, recall and F-measure had the value of 100%.

It is clear that there was not any semantic similarity technique that provided 100% accurate results. As it can be seen through Fig. 2, among the different techniques, the Cortical.io behave better since it provided less errors (13%) compared with the other semantic similarity techniques (31%, and 23% accordingly). Moreover, the F-measure (a result of both the precision and recall) of the Cortical.io had the greatest value (84%) in comparison with the other semantic similarity techniques (77%, and 65% accordingly). Consequently, this lead us to the conclusion that for the Semantic Similarity Identifier the most convenient semantic similarity technique to use is the Cortical.io, since it provides more efficient and reliable results.

Figure 2. Visualization of Comparison Results.

In the field of healthcare interoperability, semantic similarity has to be identified, for which there has been little systematic analysis on which techniques perform well when applied to ontology alignment. For addressing this gap, in this paper a previous research was considered, about a healthcare ontology matching mechanism that has the ability of transforming healthcare data to HL7 FHIR format. Therefore, based upon this research, in order to identify the required semantic similarity, three of the most well-known semantic similarity techniques were used under the same scenario, in order to result to the most efficient technique of semantic similarity in the cases of healthcare ontologies alignment, and consequently to the most efficient HL7 FHIR transformation.

To this context, we will continue working on the evaluation of the Semantic Similarity Identifier mechanism with additional semantic similarity techniques, to identify the technique that is most suitable for the case of healthcare ontologies alignment. In addition, we will continue on this evaluation with datasets of different sizes, standards and formats, respecting privacy issues, based on the mechanism developed in [8].

Abstract. The aim of this study was to develop a simple method to map the French International Statistical Classification of Diseases and Related Health Problems, 10th revision (ICD-10) with the International Classification of Diseases, 10th Revision, Clinical Modification (ICD-10 CM). We sought to map these terminologies forward (ICD-10 to ICD-10 CM) and backward (ICD-10 CM to ICD-10) and to assess the accuracy of these two mappings. We used several terminology resources such as the Unified Medical Language System (UMLS) Metathesaurus, Bioportal, the latest version available of the French ICD-10 and several official mapping files between different versions of the ICD-10. We first retrieved existing partial mapping between the ICD-10 and the ICD-10 CM. Then, we automatically matched the ICD-10 with the ICD-10-CM, using our different reference mapping files. Finally, we used manual review and natural language processing (NLP) to match labels between the two terminologies. We assessed the accuracy of both methods with a manual review of a random dataset from the results files. The overall matching was between 94.2 and 100%. The backward mapping was better than the forward one, especially regarding exact matches. In both cases, the NLP step was highly accurate. When there are no available experts from the ontology or NLP fields for multi-lingual ontology matching, this simple approach enables secondary reuse of Electronic Health Records (EHR) and billing data for research purposes in an international context.

Keywords. ICD-10, Clinical terminologies, Interoperability, Multilingual matching

1. Introduction

The International Statistical Classification of Diseases and Related Health Problems, 10th revision (WHO-ICD-10) one of the most popular terminologies used in around the world.

¹ Corresponding Author, *Faculté de médecine, Université Rennes 1, 2 Avenue du Professeur Léon Bernard 35043 Rennes Cedex 9, France*; E-mail: emmasyl@gmail.com.

It is a standard diagnostic terminology created and maintained by the World Health Organization (WHO) since 1990 for diagnostic coding[1]. The French healthcare system uses a French version of the WHO-ICD-10 (Classification Internationale des Maladies, 10e version, CIM-10) since 1997[2], while the United States created and implanted their own adaptation of the terminology (International Classification of Diseases, 10th Revision, Clinical Modification, ICD-10-CM) on October, 1st, 2015[3]. There are far more codes in the ICD-10 CM than in the CIM-10, even though they share the same common denominator: the WHO-ICD-10[3].

Multilingual ontology matching is the process of finding correspondences between ontologies of different languages to allow them to interoperate[4]. This enables secondary reuse of Electronic Health Records (EHR) and billing data from different healthcare systems for research purposes, especially if data from the United States is involved in the study. We can use two main strategies for multilingual ontology matching: direct and indirect alignment. The direct alignment is translation-based and uses external resources to help with translation, while the indirect alignment uses intermediary mappings between the source and target ontologies. Furthermore, mapping two ontologies can be an automated or manual process. Manual mapping is still the prevalent choice for ontology matching, but necessitates a large team of experts, is time-consuming, and is prone to errors[5]. On the other hand, automated approaches use public terminology resources such as the Unified Medical Language System (UMLS)[4] or Biportal[6] but those sources are extremely incomplete outside of the English speaking world[7]. Therefore, when the purpose of a study is not the mapping itself but a necessary step to join databases, it should be possible to overcome the semantic interoperability issue by combining different automated matching techniques to conduct the study, even with limited resources or experts from the ontology matching field.

The aim of this study was to develop and evaluate a simple method to link the French ICD-10 (or any version of the WHO ICD-10) with the ICD-10 CM. We sought to map these terminologies forward (ICD-10 to ICD-10 CM) and backward (ICD-10 CM to ICD-10).

2. Methods

2.1. Terminology resources

Since there were no direct mapping files for our study, we used all the intermediate mapping files available online. We used four data sources: i) the UMLS Metathesaurus, which integrates and assigns a unique identifier to synonymous concepts from several standard biomedical technologies (including ICD-10 CM, WHO-ICD-10 and a 1998 version of the CIM-10)[4], ii) Biportal, which is a comprehensive repository of standard terminologies created by the National Center for Biomedical Ontology (NCBO), with an ontology alignment tool, called Lexical OWL Ontology Matcher (LOOM)[6], iii) the latest version of the CIM-10, which is mainly a translation of the WHO-ICD-10 with more children, and is publicly available on the national billing agency website (Agence Technique de l'Information sur l'Hospitalisation, ATIH)[2] and iv) different existing mapping files with forward and backward mapping such as: the General Equivalent Mapping (GEM) Files from the National Center for Health Statistics (NCHS)[8], the New-Zealand mapping files from the Ministry of Health (ICD-10 Australian Modification and ICD-9 Australian Modification)[9] and the mapping files between the

ICD-10 AM and ICD-10, from the Australian Consortium for Classification Development (ACCD)[10].

2.2. Mapping method

We decided to map only the first 4-character codes of the CIM-10, because the WHO-ICD-10 is mainly 4-character codes, except for chapters XIII, XIX, XX, which means that after this position, there was a bigger risk of mapping codes with a different signification between the two languages.

Our strategy used three main steps (Figure 1). First, we used the NCBO API to retrieve the mapping between the ICD-10 CM and the WHO-ICD-10 and the partial mapping between the CIM-10 and the WHO-ICD-10 from the UMLS Metathesaurus and LOOM algorithm, which is available through the NCBO API. Then, we matched each terminology using the different mapping files mentioned above. And finally, we used manual review and natural language processing (NLP) to recognize labels between the two terminologies with custom R scripts. The NLP process was only used on unmatched codes after the two first steps. For each set, one native-speaking investigator from each language extracted the two or three main words of the ICD or CIM label, then they built together a translation dictionary and used rules-based NLP to match the labels and codes. For the remaining unmatched codes, we mapped them to their three-character codes parent. After all these steps, we considered the code unmatched if we could not find an exact or approximate match.

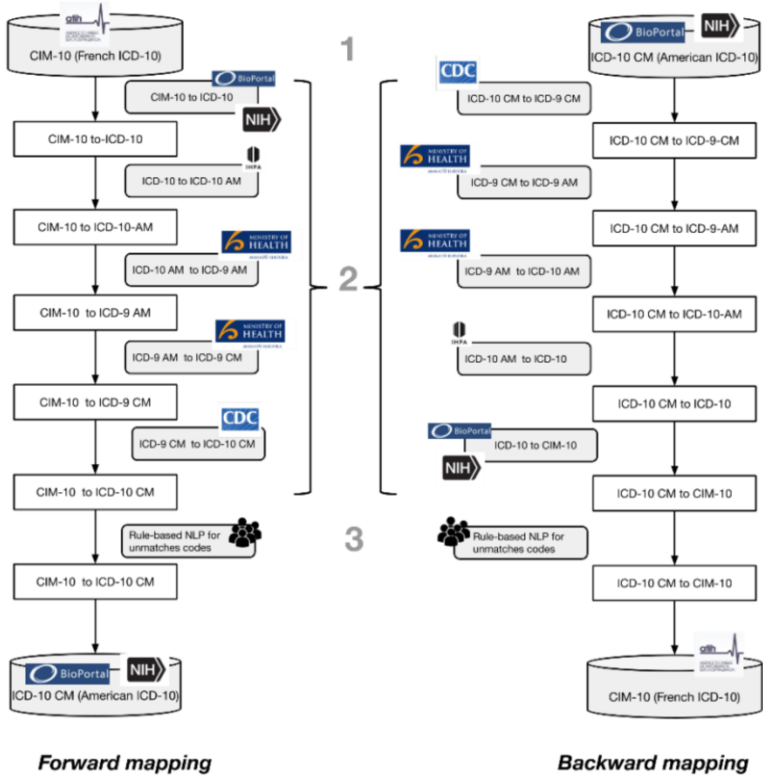

Figure 1. Forward and backward mapping methods

Since the automated mapping was based on official mapping files, we did not review those matched codes. However, we reviewed manually all NLP-based matches before confirming their match or un-match status. Uncertain pairs were reviewed again by two other medical investigators.

3. Results

The ICD-10 CM included 91,737 codes and the French ICD-10 included 39,928 codes, including the 3-characters codes parents. The ICD-10 CM had 9835 (11%) of 4-characters codes while the ICD-10 had 12,345 (31%) of 4-character codes.

Among the 39,928 codes of the CIM-10, 8,477 (21.2%) were exact matches to the ICD-10 CM and 29,131 (73 %) were partial matches. 264 of those partial matches were based on the NLP-based step. There were 2,320 (5.8%) missing codes.

Among the 91,737 codes of the ICD-10 CM, 9,082 (9.9%) were exact matches and 82,655 (90.1 %) partial matches with no unmatched codes. 226 of those partial matches were based on the NLP-based step. There were no missing codes.

All the NLP-based matches were true positives with no false negatives. Overall, the backward mapping was 94.2%, while the forward mapping was 100%. (Table 1)

Table 1. Characteristics of all matches after the forward and backward mappings

Mapping	Exact Match	Partial Match*				No match
		>4-characters code to one 4-character code	>4-characters code to more than one 4-characters code	4-characters code to more than one 4-characters code	4-characters codes (or more) to the 3-characters parent	
ICD-10 to ICD-10 CM	8,477 (21.2%)	4,832 (12.1%)	23,345 (58.5%)	932 (2.3%)	22 (0.1%)	2,320 (5.8%)
ICD-10CM to ICD-10	9,082 (9.9%)	41,518 (45.3%)	33,893 (36.9%)	1,797 (2%)	5,447 (5.9%)	0 (0%)

*The partial match includes the codes matched using the Natural Language Processing (NLP) step

4. Discussion

Our method showed a very high matching score, especially regarding the backward mapping (ICD-10 CM to ICD-10) with 100% of codes matched. However, the exact match was far better in the forward mapping (21% versus 10% in the backward). The manual evaluation confirmed the accuracy of the rules-based NLP algorithm.

Our study has several limitations. First, we only tested the method with two languages (French and English). However, we only had native speaking experts in French and English available for the manual review and most countries use either the ICD-10 CM, or a fairly close version of the WHO ICD-10 for reimbursement and billing[1]. Therefore, we knew that if our mapping process was accurate it would be relatively easy to adapt it to other languages. Second, our NLP was rather basic because we wanted first and foremost to use already existing reference files. Previous studies[11,12] showed that NLP based on modern machine-learning methods is the most pertinent method to match a diagnostic to an ICD-10 code or to translate a terminology to another language, but it is a very specific field with few experts, especially outside of the English language. The idea here was to propose an alternative when NLP specialists are not available to implement automatic translation and/or matching algorithms. Finally, most of our matches are partial. A majority of exact matches would have been ideal,

especially since the ICD-10 is not always very precise regarding some diagnoses[13], but since the WHO-ICD-10 and the ICD-10-CM have a vastly different number of codes[3], this outcome was predictable.

Manual mapping for multilingual ontology alignment is still the gold standard today, but it requires several experts of the healthcare and ontology fields and is a very time-consuming work that can take years[14]. This method cannot make the same claims of precision as official manual mapping files, but it could become a fairly quick and reliable process for international studies based on secondary reuse of EHR and billing data (including legacy data coded in ICD-9 CM, thanks to the GEM files from the NCHS[8]) without any ontology or translation experts.

5. Conclusion

Our study demonstrated that semi-automated mapping based on reference mapping files (in standard format) and basic NLP could be considered for secondary reuse of EHR and billing data from different countries when there are no existing reference files. Next, we would like to replicate this study with ICD-10 in other languages and use more automated NLP resources, like the Google Translate API, to confirm the accuracy of this method. This work could also serve as a basis for semi-automated mapping of the ICD-10 to the ICD-11, once the official ICD-10 to ICD-11 mapping files are available.

Abstract. The acquisition of medical images from multiple medical institutions has become important for high-quality clinical studies. In recent years, electronic data submission has enabled the transmission of image data to independent institutions more quickly and easily than before. However, the selection, anonymization, and transmission of medical images still require human resources in the form of clinical research collaborators. In this study, we developed an image collection system that works with the electronic data capture (EDC) system. In this image collection system, medical images are selected based on EDC input information, patient ID is anonymized to a subject ID issued by the EDC, and the selected anonymized images are transferred to the research institute without human intervention. In the research institute, clinical information registered by the EDC and clinical images collected by the image collection system are managed by the same subject ID and can be used for clinical studies. In October 2019, our image collection system was introduced to 13 medical institutions and has now begun collecting medical images from the in-hospital picture archiving and communication system (PACS) of those institutions.

Keywords. Multicenter clinical study, Electronic data submission, Medical image

1. Introduction

Assessments of medical images are often needed in multicenter clinical studies. To ensure the quality of image analyses, imaging core labs that collect medical images taken at multiple medical institutions in one place and analyze them in a defined way are needed [1, 2]. Regarding image analyses by artificial intelligence (AI), a large amount of medical images are required [3, 4]. For this reason, a system that supports efficient image collection from independent institutions is required.

For the protection of patient information, medical images used for clinical research must be anonymized at each medical institution. Medical images stored in the digital imaging and communications in medicine (DICOM) standard can be anonymized by rewriting the DICOM tag information. However, in a non-DICOM image, patient information is described in the image, and it is necessary to erase patient information by image processing for anonymization.

¹ Corresponding Author, Toshihiro Takeda, Department of Medical Informatics, Osaka University Graduate School of Medicine, 2-2 Yamada-oka Suita Osaka 565-0871 Japan, E-mail: ttakeda@hp-info.med.osaka-u.ac.jp

Clinical information must be collected in addition to images for subsequent analyses. Such clinical information is often collected via an electronic data capture (EDC) system [5, 6]. In EDC system, anonymization is usually performed by replacing the patient ID with the subject ID. For efficient data analyses in a research institute, the anonymization of clinical images is also performed using the same subject ID.

In recent years, electronic data submission has enabled the transmission of image data to independent institutions more quickly and easily than before [7]. However, research collaborators in each institution still need to select the medical images, anonymize the patient information, and perform the electronic transfer itself. When it is difficult to replace the patient ID with the subject ID, a correspondence table must be created between the image anonymization ID and the subject ID and sent to the relevant research institute. These tasks require substantial effort from research collaborators, who are already busy with their clinical work.

We developed an EDC system that collects clinical information in cooperation with electronic medical records (EMRs) [8]. The doctors in each collaborating institution enter clinical information via template of the EDC system which can retrieve the data recorded in the EMR. The EDC system outputs narrative text of input data to the progress note of the EMR. The EDC system also maps the input data to the operational data model (ODM) developed by Clinical Data Interchange Standard Consortium (CDISC) and sends to the research institute. The EDC site server anonymizes the patient ID and issues a subject ID, maintaining a correspondence table of the patient and subject IDs.

In the present study, we developed an image collection system that works with our EDC system. In this image collection system, medical images are selected based on EDC input information, a patient ID is anonymized to a subject ID issued by the EDC system and the selected anonymized medical images are transfer to the research institutes.

2. System Overview

The image collection system is divided into image acquisition from the picture archiving and communication system (PACS) and that from non-DICOM server. The EDC site server and the image acquisition gateway were set up in each collaborating institution (Figure 1), while the EDC center server and image-receiving server were set up in the research institute. A virtual private network (VPN) internet connection was used for connections between the research institute and each medical institution.

Figure 1. System overview

3. Collection of images stored in the DICOM standard in prospective studies

3.1. Image acquisition and anonymization by the image acquisition gateway

The image acquisition gateway asks the EDC site server about image information to be acquired. This information includes the patient ID, observation date, modality, and observation area. The subject ID is also obtained at this time. Next, the gateway searches the PACS for the target images using a query and retrieve (Q/R) connection. The patient ID described in the DICOM tag of the acquired images is then anonymized by replacing it with the subject ID issued by the EDC system. Finally, the gateway transfers the anonymized images to the image receiving server in the research institute.

3.2. Transmission of information from the EDC to the image acquisition gateway

Our EDC system is designed to enter clinical information using templates for each event. For the image to be collected, the item of “observation date” is set in the template. When a study using collected images is registered to the EDC, the EDC outputs the ODM files of the input template data to the predetermined folder at a time fixed by the scheduler (Figure 2). The output ODM file name is composed of the “patient ID”, “Study OID”, “Event OID”, “ODM file output date and time”. “Subject ID”, and input data, including the “observation date”, are described in the ODM file.

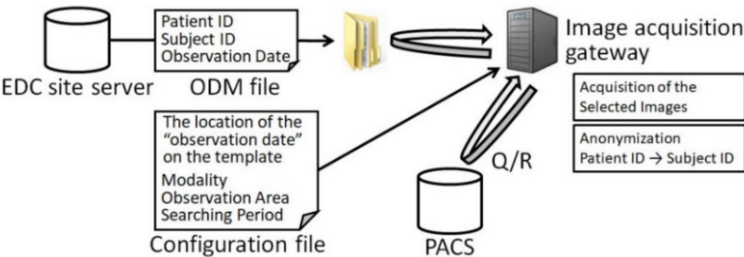

Figure 2. Transmission of information from the EDC to the image acquisition gateway

We defined the configuration file for collecting images beforehand and registered it to the image acquisition gateway. In the configuration file, information about the location of the “observation date” described on the template are defined. The location is identified by the “Study Code”, “Study Event OID”, “Form OID”, “Item Group OID”, and “Item Data OID”. In the configuration file, the “modality”, “observation area”, and “search period” based on the “observation date” are also defined. The image acquisition gateway acquires search conditions for images to be acquired from the ODM file output by the EDC system and the configuration file registered beforehand and searches for images stored in the in-hospital PACS. Figure 3 shows an example of a configuration file for extracting images from the in-hospital PACS.

Study Code	Study Name	Image Identification Name	Modality	Observation Area	Study Event OID	Form OID	Item Group OID	Item Data OID	Search Period		Comment	Destination	Status 0: waiting 1: stopped
									Pre	Post			
VS4	VS4 study	Preoperative CT	CT	CHEST	SE PREOP	F.CT	IG.CT	ID.CT DAT	6	1	CT images taken just before surgery	A00	0
VS4	VS4 study	Postoperative CT (1M)	CT	CHEST	SE 1M	F.CT	IG.CT	ID.CT DAT	3	4	CT images taken 1 month after surgery	A00	0

Figure 3. The EDC template and its configuration file for collecting images

4. Collection of images stored in the non-DICOM standard

For the collection of non-DICOM images, the research collaborators must select the images and output them to a specific folder (Figure 1). Next, the patient information described in the selected images is masked using the image acquisition software program. This program can set a plurality of masking patterns in advance, and one of them is set as the main masking pattern for each project. After masking the patient information, the images are converted to the DICOM format, and the patient IDs in the DICOM tag are anonymized to the subject IDs issued by the EDC system. The images are then transferred to the image-receiving server placed in the research institute.

The application can collect the image information from the image folder and file name. There are two patterns for collecting image information: (1) a pattern that sets a delimiter and corresponds to variable-length information, and (2) a pattern that does not set a delimiter and corresponds to fixed-length information. Figure 4 shows an example of the image information collected from a folder and file name.

Figure 4. Collection of the non-DICOM image information

5. Collection of images stored in the DICOM standard in retrospective studies

Images obtained in the past may need to be collected in bulk, such as for image analyses using AI. However, as the PACS is designed to be used on a per-patient basis, the selection and download of images must be performed by launching the PACS viewer for each patient. The image collection system can batch download medical images, anonymize the patient ID to the subject ID, and send the images to the research institute according to the acquisition conditions defined in the csv format file.

6. Introduction status of our image collection system

On October 1, 2019, our image collection system was introduced to 13 medical institution, and medical images began to be collected from these centers' in-hospital PACS, which had been developed by 4 PACS manufacturers.

7. Discussion

As discrepancies may occur between the image analysis results assessed by an imaging core lab and those obtained by study sites, it is necessary to collect images at a single institute to maintain the quality of clinical research involving image analyses [1].

Although the submission of imaging data in an electronic format has begun to spread, the tasks of selecting, anonymizing, and transferring data still pose a substantial burden to research collaborators. This results in a limited number of medical institutions cooperating in image collection. Our image collection system selects the images to be collected, anonymizes the patient information, and transfers them to the research institute. Since the images to be collected are determined on a study-by-study basis, the modality and observation area of the images are entered into the configuration file and registered in the image acquisition gateway, so that research collaborators only need to add the observation date of the images to the EDC template. This image collection system may facilitate multi-center clinical studies.

For images stored in the DICOM format, patient information is only described in the DICOM tag. Therefore, automatic anonymization can be easily achieved. In contrast, the images stored in the non-DICOM format may include sensitive patient information, so image processing is necessary for anonymization. To ensure reliable anonymization, automatic anonymization should not be performed. However, setting the masking area and performing the automatic acquisition of image information from the folder and file names will assist in collecting non-DICOM images.

8. Conclusion

We developed an image collection system that automatically selects, anonymizes, and transfers medical images based on the EDC input information.

An Evolutionary Approach to the Annotation of Discharge Summaries

Christina LOHR^{1ab}, Luise MODERSOHN^{ab}, Johannes HELLRICH^{ab}, Tobias KOLDITZ^{ab}, Udo HAHN^{ab}

^a*Jena University Language & Information Engineering (JULIE) Lab Friedrich-Schiller-Universität Jena, Germany*

^b*SMITH Consortium of the German Medical Informatics Initiative*

Abstract. We here describe the evolution of annotation guidelines for major clinical named entities, namely *Diagnosis*, *Findings* and *Symptoms*, on a corpus of approximately 1,000 German discharge letters. Due to their intrinsic opaqueness and complexity, clinical annotation tasks require continuous guideline tuning, beginning from the initial definition of crucial entities and the subsequent iterative evolution of guidelines based on empirical evidence. We describe rationales for adaptation, with focus on several metrical criteria and task-centered clinical constraints

Keywords. Clinical text corpus, German discharge summaries, Annotation guideline

1. Introduction

The annotation of clinical documents is a challenging task due to the intrinsic opaqueness and complexity of the clinical domain. Clinical experts do not necessarily agree on fundamental judgments relevant for annotation decisions, e.g., the distinction between symptoms, diagnoses and other medically relevant phenomena. Reports of medical annotation campaigns often disregard this lack of conclusiveness insofar as the painstaking adaptive processes underlying the vernier adjustment of annotation guidelines are hidden from the scientific community. Most often only the final outcome of consensus-seeking processes is made publicly available. Annotated clinical text corpora focusing on diagnoses came up with clinical shared tasks, e.g., I2B2 [1], CLEF eHEALTH [2], and SEMEVAL [3]. The annotation of major clinical entities is typically considered as a very hard decision task, with agreement scores (*F*-scores, κ - or α -values) usually in the range between 0.7 and 0.8, even after several modification rounds for annotation guidelines (see Table 1 for an overview of previous annotation campaigns related to clinical documents).

We here want to shed light on the impact of different annotation policies and propose robust metrical decision criteria in order to find out which kinds of adaptive steps have particular impact on annotators' (dis)agreement and how such factors can be controlled by empirical evidence. We illustrate an evolutionary approach to the development of

¹ Corresponding Author: email: christina.lohr@uni-jena.de

annotation guidelines for major clinical named entities, namely *Diagnoses*, *Findings* and *Symptoms*, on a corpus of roughly 1,000 German discharge summaries.

Table 1. Overview of clinical annotation studies, incl. annotated entities and agreement scores (F -score, Cohen’s κ (κ_c), Siegel and Castellan’s κ (κ_{sc}) or Krippendorff’s α)

Authors	Data	Annotated Entities	Agreement

He et al. [15]	138 Chinese documents		$F = 0.992$

2. Methods

Data and Annotation Setup. This work was carried out on the Jena part of the 3000PA text corpus [16]—1,106 German discharge summaries from the Jena University Hospital’s information system given the following constraints: patients had stayed for at least five days on a ward for internal medicine or in an intensive care unit between 2010 and 2015, and were already deceased. These criteria were approved by the local ethics committee (4639-12/15). The corpus consists of approx. 170K sentences and 1.5M tokens. The documents were annotated (using the *Brat Rapid Annotation Tool*)² by eight medical students who all had passed their first medical licensing exam. We ran through four iterations of guideline revisions, tool configuration, team instruction, annotation work, agreement computation, error analysis and subsequent team discussion. This process was supervised by one annotation manager. In each iteration, 5 to 10 documents and 50 in the final round were annotated by each student (for agreement values see Table 2).

Evaluation Measures. A challenging problem for medical annotations is posed by determining the proper text span of named entities. We thus calculate inter-annotator agreement (IAA) by using the pair-wise average F -score [17] of instances and tokens. An *instance* is a single composite annotation unit that consists of one or more tokens (e.g., “renal insufficiency” denotes an instance with two tokens, “renal” and “insufficiency”). Instance agreement is a strong criterion, as annotations with only slightly differing spans

² <https://brat.nlplab.org/>

count as non-matching. Token-based agreement describes the overlap of individual tokens for annotations of the same instance type³.

Table 2. Inter-annotator agreement (IAA; pair-wise average F-score incl. standard deviation (σ)) of training iterations and the final annotation round (incl. the number of documents being used per iteration (in brackets)), for each document over all eight annotators w.r.t. instances (inst.) and tokens (tok.)

	Iteration 1 (10)		Iteration 2 (5)		Iteration 3 (10)		Iteration 4 (10)		Final (50)	
Category	inst.	tok.	inst.	tok.	inst.	tok.	inst.	tok.	inst.	tok.
Diagnosis	.504	.633	.534	.630	.593	.705	.614	.688	0.637	0.758
Findings	.354	.545	.698	.896	.682	.887	.628	.864	0.684	0.860
Symptoms	.583	.617	.441	.657	.424	.729	.532	.669	0.611	0.718
Anatom. Loc.	.455	.624	.735	.876						
Procedures	.252	.301	.527	.580						
Avg. F-score	.410	.563	.671	.832	.653	.873	.621	.837	.648	.839
σ (F-score)	.079	.076	.056	.030	.064	.027	.065	.036	.056	.032

Annotation Schema. We started our annotation campaign with five types of medical entities: *Diagnosis* as *diseases* as listed in the ICD-10 (excluding symptom chapter ‘R’); *Findings* as the summary of all information about a patient’s medical status reported by medical staff based on the results from physical examination or the use of medical devices (e.g., x-ray); *Symptoms* as the summary of all health affecting information and complaints reported by the patients or their relatives; *Anatomical Location* as the summary of all anatomical parts of the body excluding body fluids and body secretions; *Procedures* as the summary of all medical interventions like surgery, non-surgical therapeutic measures, etc. The administration of (new) medication belongs to the latter category, but was excluded here since medication had already been annotated elsewhere[16].

Iterative Process. The average agreement value (*F*-score) of the first iteration reached .410 on instances and .563 on tokens which is clearly below expectations. During the second iteration *Anatomical Locations* were automatically pre-annotated based on the German part of the *Foundational Model of Anatomy (FMA)* of the UMLS using the JUFIT tool. This step increased the IAA for *Anatomical Location* up to .735 on instances and .876 on tokens. Still, it was removed from further annotation rounds because of its overlap with mentions of *Diagnoses*, *Findings* or *Symptoms*. Also discussions with the annotators pointed at a painfully large number of single decisions and double annotations to be made resulting in an average annotation time of one hour per document. In particular, distinguishing *Procedures* from *Medications* (e.g., “long-term oxygen therapy”) and *Diagnoses* was considered a difficult task—a previous intervention can be coded as *Procedures* and *Diagnoses* (e.g., Z98.8—Other specified postsurgical states). As a clear criterion to minimize the overlap between *Diagnoses* and *Procedures* could not be found we eliminated *Procedures* from the current annotation project and will deal with it separately. Following the approach of Hahn et al. [8] for annotating long and short text spans, we required the attribute *Complexity* to be tagged for all entities containing more than one piece of annotation-relevant information (e.g., “Pupils middle and isocor”). *Diagnosis*, *Symptoms* and *Findings* were assigned two attributes: *Time* with the value set *previous*, *recurrent*, *uncertain* and *Modality* with the value set *suspected*, *excluded*, *uncertain*. Negations or vague descriptions were defined to be part of the long annotation span.

³ We used TREE TAGGER, accessible via <https://www.cis.uni-muenchen.de/~schmid/tools/TreeTagger/>

Baseline Classifier. We trained a (CRF-based) JCORE pipeline for named entity recognition of *Diagnosis*, *Findings* and *Symptoms*; evaluation with 10-fold cross-validation.

Table 3. Instances and tokens of entity types *Diagnosis*, *Findings*, *Symptoms*, with the percentage distribution of their attributes *Complexity*, *Modality*, *Time*; baseline classifier (BC) results (avg. token distribution depending on all of the 1.863M tokens; all other percentage values depending on the total number of entity instances)

	Inst.	Tokens		Avg. span	Complexity	Modality			Time			BC
						sus.	exc.	unc.	rec.	unc.	pre.

3. Results

The final average IAA values were .648 on instances and .839 on tokens (see Table 2). Table 3 illustrates the distribution of the different entities and their attributes. About one third of the entire corpus consists of *Findings*. *Diagnoses* added up to around 6.6%, whereas *Symptoms* were rare with less than 2%. Around 13% of all annotations were marked as *complex*; roughly every fifth instance of *Findings* and *Symptoms* contained more than one information unit. Compared to *Findings* and *Symptoms*, *Diagnoses* were more precisely described. 10–20% of all annotations were *negated*. The majority of negated entities were *Symptoms* and *Findings* ($\approx 20\%$). The attributes *suspected* and *uncertain* were rarely used, only about 5% of *Diagnosis* annotations were marked as *suspected*. Temporal annotations of *Findings* and *Symptoms* were hardly used, $\approx 7\%$ of *Diagnoses* were *previous*. The average *F*-score results of our (admittedly simple) CRF-based classifier are .805 for *Findings*, .475 for *Diagnosis* and .143 for *Symptoms*.

4. Discussion

The final IAA values (0.7–0.8) could be improved and are comparable to, if not higher than, annotation campaigns covering the listed entity types in languages other than German (cf. Table 1). Category overlap or hard to disentangle semantic interdependencies must be resolved for the sake of acceptable IAA values—either by generalizing category definitions, by stretching the granularity of annotation spans, by adding complexity markers (thus delegating finer distinctions to future annotation studies), or, in the worst case, by eliminating sloppy named entity types from the current annotation process.

5. Conclusion

We presented an evolutionary approach to an annotation scheme for *Diagnoses*, *Findings* and *Symptoms* and its application to German discharge summaries. We struggled with

criteria that control the number of iterations and the directions of adaptations. Generalizing from the our annotation task, we found that IAA is a solid metrical indicator for task complexity or inconclusive annotation guidelines. Both parameters have to be tuned in case of too low IAA values. Annotation time is a metrical indicator for task complexity.

Abstract. Development of vascular collaterals in a lesion area is one of the key factors that determine not only the choice of treatment for ischemic stroke (IS) patients, but also outcome and therapy effectiveness. The main method for examining the vessels' ramification is CT angiography (CTA). CTA analysis may be improved by incorporating filters designed to extract more features about vessels and quantify their level of development. This work suggests the usage of radiomics methods in the analysis of vesselness measure calculated from CTA images. Vesselness measurement is based on the analysis of the Hessian matrix with a few modifications dictated by practical aspects of this issue. The developed algorithm was implemented as a filter that generates a new 3D image, every voxel of which has the probability of belonging to a vessel-like structure. Further analysis of the distribution of vesselness in the lesion area and in the intact contralateral area was conducted with the methods from the open library PyRadiomics. A set of radiomics features was calculated. Preliminary analysis on a sample of 30 IS patients showed the presence of significant differences between afflicted and intact hemispheres.

Keywords. Collaterals, imaging biomarkers, ischemia, tomography

1. Introduction

Ischemic stroke (IS) is one of the leading causes of death and disability in the world [1]. The outcome of IS depends not only on the timeliness of the reperfusion therapy but also on the intensity of collateral flow [2]. The absence of well-developed collaterals leads to an increase in the volume of necrotized tissue and to a decrease in the effectiveness of treatment [3]. In daily practice, CT angiography (CTA) is used as the main method for visualizing of vascular anatomy. However, it is very common among radiologists to analyse CTA images manually, resulting in subjectivity of the assessment. Cutting-edge methods of image processing, including vesselness calculation algorithms, may be of help in addressing this problem, by providing an automatic measure of collateral status.

Vesselness calculation involves assessment of the probability of each voxel belonging to a vessel-like structure [4]. According to literature, there is a possibility of using vesselness to resolve some clinical challenges in treatment of IS patients [5-7]. Currently, most of studies include analysis of variables based only on the volume of vessel-like structures, but not on their spatial behavior and other characteristics. At the same time, one of the most perspective directions of modern medicine is the analysis of radiological images, specifically radiomics [8-10]. It allows extracting numerous features including those that describe shape and texture from radiological images. So, in the line with the above, the aim of the presented work was the application of radiomics methods in the analysis of vascular behavior calculated from the CTA images of the patients with IS.

2. Methods

This pilot study included data of 30 patients (74 years old (IQR 57-80), 18 males, 12 females) admitted to the N.V. Sklifosovskiy Scientific Research Institute of Emergency Care with IS in the territory of the middle cerebral artery (up to 5 hours from stroke onset). The examination of the patients was performed with multi-slice CT-scanner (GE Medical Systems), with pixel spacing of 0.44 x 0.44 mm, and slice thickness of 0.5 mm. We used CTA images obtained on the admission of a patient to the hospital, and images from non-enhanced CT conducted on the second day after IS onset, when the ischemic region was already visible as a hyperdense area. The last ones were used for contouring of the regions of interest (ROI) that was conducted by two radiologists (Figure 1, A). Each of them had more than 20 years of experience.

Brain normalisation was conducted to build a symmetrical area and to transfer both areas (with damaged and intact brain tissues) onto the CTA series (Figure 1, B and D). It was performed with the set of instruments described in the Advanced normalisation tools (ANTS) [11] that allowed coregistration of a brain to a template image using linear affine and warp transformations.

Then, CTA images were processed through the vesselness filter (Figure 1, C). The vesselness calculation was based on the following key concept: if we look at every voxel of a 3D image and evaluate the function of the derivative of intensity along three orthonormal directions, then it is possible to establish criteria for a voxel belonging to a tubular structure. The mathematical representation of this is the Hessian matrix calculation with second-order partial derivatives, and the assessment of its three eigenvalues λ_1 , λ_2 , λ_3 sorted in ascending order [4]. This method successfully identifies vessels, but it causes a decline of vesselness value in vessel bifurcation points. To address this issue, [7] proposed using λ_p as a regularized value, which is computed depending on the maximal value of λ_3 .

Based on the latter, we developed a vesselness filter, but made some changes to adaptation to further clinical research work. First, as the original CT images are noisy, it was necessary to smooth them to make them better suited for vessel analysis. The minimisation of noise is determined by the size of vessels that we are looking for and by the resolution of the CT scanner (0.7-1.4 mm). Thus, we applied the Gaussian filter with $\sigma=0.7$ mm. This allowed us to determine the Hessian matrix more robustly while keeping information about small vessels. Second, we adapted the approach proposed in [7] to λ_p regularization. λ_p depends on the maximal value of λ_3 throughout an image. In this case, even if we have a fairly smooth image with relatively meagre vascularity, we find a lot

of vessel-like structures. So, the results of vesselness analysis for different images and patients are not comparable. To avoid this, we decided to exclude the dynamic nature of λ_p and fix the maximum value of λ_3 at 400 HU/mm². The filter was implemented in our previously developed platform for medical images analysis [12].

The initial CTA images of 30 patients were processed through it, and new 3D images were generated. Each voxel has a vesselness value which measures the similarity of the voxel to a vessel-like structure. As the total sum of vessel-like voxels is very sensitive to the threshold of vesselness, we decided to implement the calculation of other features of the filtered images, describing other morphometric and distribution aspects of vesselness. The open library PyRadiomics was used to calculate 75 features of damaged and intact areas [13-14]. They included first-order statistics (FO) and second-order statistics which were based on analysis of the grey-level co-occurrence (GLCM), grey-level size zone (GLSZM), and grey-level run-length (GLRLM) matrices.

Figure 1. Scheme of the image processing for the calculation of radiomics features of vesselness (A – semiautomatic segmentation of ROI with damaged tissue on non-enhanced CT, B – automatic segmentation of ROI in the intact area, C – Application of vesselness filter on CTA images, D – copy of two ROIs to the filtered CTA images)

3. Results

Comparative analysis of 75 features in damaged and intact areas of 30 patients showed the presence of statistically significant differences in 57 parameters ($p < .05$, the Wilcoxon signed-rank test). For 48 of them these differences were highly significant ($p < .001$). We evaluated their relative change against the intact side to select the most informative features. It the confidence interval of a feature's relative change contained zero, the feature was excluded. Thus, the following list of features with the most pronounced and stable changes was formed (Table 1).

Table 1. The magnitude of the features' relative change in comparison with intact area.

Feature Group	Feature Name	Relative change	P-value
FO	Energy	↓ 79.3 (IQR 12.3-91.0) %	<<0.001
	Variance	↓ 79.6 (IQR 11.1-91.2) %	<<0.001
	Entropy	↓ 34.9 (IQR 11.1-91.2) %	<<0.001
GLCM	Contrast	↓ 81.4 (IQR 21.9-47.7) %	<<0.001
	Difference Variance	↓ 81.5 (IQR 21.0-91.0) %	<<0.001
	Joint Entropy	↓ 34.5 (IQR 23.3-47.3) %	<<0.001
GLRLM	High Grey Level Run Emphasis	↓ 72.0 (IQR 10.0-84.6) %	<<0.001
GLSZM	Large Area Emphasis	↑ 133.2 (IQR 10.9-228.1) %	<<0.001
	Size-Zone Non-Uniformity	↓ 71.9 (IQR 14.9-84.9) %	<<0.001
	Zone Variance	↑ 133.1 (IQR 10.9-228.0) %	<<0.001

As you can see in the table 1, the damaged areas show a decrease in energy and variance as a result of reduction in the number of vessel-like voxels. GLCM features indicated a decrease in the homogeneous patterns in the image. Changes in size-zone non-uniformity and zone variance of GLSZM reflect the fact that the distribution of zones with the same intensity level was modified in the damaged ROIs.

4. Discussion

One of the most effective ways to improve the quality of treatment for IS patients is to implement the advanced technologies of intellectual analysis and image processing into interpretation of the results of neuroimaging examinations. Assessment of the collateral status on the CTA allows predicting effectiveness of revascularization surgeries and long-term outcome of a clinical case, hence providing the decision support in the choosing of the treatment tactics for patients.

In this work we detected a large difference between damaged and intact areas in 10 features describing vesselness behavior. An interesting aspect of these preliminary results was that some of these features indirectly described the volume of vascular tree or a number of bright voxels (e.g., energy, variance, root mean squared), but others outlined the homogeneity of regions of interest (e.g., entropy, contrast of GLCM, size-zone non-uniformity and zone variance of GLSZM).

It is important to note that with the application of radiomics methods to the initial images of CTA it is difficult to explain whether the discovered differences in the features are caused by the changes in vessels or in the brain tissue. At the same time, the physiological interpretation of the images resulting from the use of the vesselness filter is simpler as all changes are only related to voxels of vessels.

Limitations to this study include its retrospective design and a small sample size. Also, we didn't have a control group to investigate the behavior of the features for healthy people. In the future work we will try to address these limitations.

5. Conclusion

In this paper, we presented a method of quantitative assessment of collaterals based on the analysis of vesselness measure. The suggested procedure includes the calculation of vesselness with an algorithm developed by Jerman et al, modified by using Gaussian filters and fixing the maximum value of λ_3 . The result of the application of the vesselness

filter is proposed to analyse with the radiomics methods, effectively investigating not only the volumetric characteristics of vesselness, but also the pattern of its distribution. Comparison analysis of extracted features of vesselness between the afflicted and the intact ROIs had shown that there are significant differences in a number of parameters. This makes it possible to develop clinically relevant measures for assessment of collaterals and prediction of treatment outcomes in further work.

^c*Department of Nursing Science University Hospital Munich, Germany*

Abstract. Nursing Minimum Data Sets (NMDS) intend to systematically describe nursing care. Until now NMDS have been populated with nursing data by manual data ascertainment which is inefficient. The objective of this work was to evaluate an automated mapping pipeline for transforming nursing data into an NMDS. We used LEP Nursing 3 data as source data and the Austrian and German NMDS as target formats. Based on a human expert mapping between LEP and NMDS, an automated data mapping algorithm was developed and implemented in an automatic mapping pipeline. The results show that most LEP nursing interventions can be matched to the NMDS-AT and G-NMDS and that a fully automated mapping process from LEP Nursing 3 data to NMDS-AT performs effectively and very efficiently. The shown approach can also be used to map different nursing classifications and to automatically transform point-of-care nursing data into nursing minimum data sets.

Keywords. nursing minimum data sets, data mapping, secondary use of nursing data, electronic health record, standardized nursing terminology, health informatics

1. Introduction

Nursing data must be documented in a standardized and structured way in Electronic Health Records (EHR) to allow meaningful data exchange in an eHealth environment. Structured electronic documentation also enables reuse of data from the nursing process for multiple purposes such as quality management or research ("Collect once, use many times" paradigm) [1]. *LEP Nursing 3* ("Leistungserfassung in der Pflege", i.e. nursing workload measurement) is a classification of around 500 nursing interventions. It allows structured care planning and documentation, together with nursing workload measurements [2]. At the moment, around 650 health care services in Germany, Switzerland, and Austria are using LEP in their EHR and for statistical evaluations of nursing data. LEP is semantically based on International Classification for Nursing Practice (ICNP) and is structured according to ISO-18104 [3].

Nursing Minimum Data Sets (NMDS) have been proposed to systematically describe nursing care and defined as '*systematic registration of the smallest possible number of unequivocally coded data, with respect to or for the purpose of nursing*

¹ Corresponding Author: Renate Ranegger, 9000 St. Gallen, Switzerland, renate.ranegger@lep.ch

practice, making information available to the largest possible group of users according to a broad range of information requirement' [4].

NMDS aim at supporting nursing managers, health policy decision-makers, public health experts, and nursing researchers [5]. They may lead to following benefits: access to comparable nursing care data on a local, regional, national, and international level; description of nursing care in different populations and variety of settings; availability of data for research activities; evaluation of costs and outcomes of nursing care; benchmarking of nursing quality indicators; extrapolation of trends in nursing care; and allocation of resources of hospitals [6, 7, 8].

In Austria, the NMDS-AT [8, 9, 10] and in Germany the G-NMDS [11] have been developed in recent years. However, up to now these NMDS were only theoretical constructs and weren't populated with nursing data due to two main reasons: First, as terminologies used in EHRs may be different from NMDS elements, a mapping between different terminology systems is necessary. Second, the usual way to populate NMDS by manual data ascertainment is time- and resource-intensive.

The objective of this work was to evaluate an automated mapping pipeline for transforming nursing data documented via *LEP Nursing 3* into the Austrian and German NMDS. This pipeline should comprise an automated mapping process for transforming *LEP Nursing 3* data into an NMDS representation and then loading it into the respective Nursing Minimum Data Set.

2. Methods and Materials

2.1. Human Expert Mapping between LEP and NMDS

For the manual expert mapping, three raters with LEP and NMDS expert knowledge were recruited. First, a training session was held to brief the mapping method. In the following first mapping round the source terminology, *LEP Nursing 3.3.1*, was matched to the target formats NMDS-AT and G-NMDS independently by all three raters. After that, questions which emerged during the first round and uncertainties concerning special mapping rules were discussed and solved in a further briefing session. Then, in a second mapping round, the expert mapping was finalized independently by all experts. Resulting discrepancies were clarified in a subsequent consensus process [12].

LEP nursing interventions offer sufficiently structured information for the mapping because LEP is based on ISO reference terminology. The NMDS nursing interventions provide additional structural elements compared to LEP and ISO. For example, LEP defines the intervention "Performing a full body wash" which related to the NMDS term "Body care washbasin/bed/incubator, partial assistance"; in this case, NMDS distinguishes the degree of dependency as an additional attribute. Therefore, the mapping was supplemented with data describing the patient condition using ICNP and the International Classification of Diseases (ICD). For example, nursing assessment data, nursing diagnoses or medical information were added to guide the mapping.

As the mapping of LEP to NMDS includes 1:n matches, interrater reliability was assessed using a specially defined metric. The metric for each mapped concept ranged from 0 (no match) to 1 (full match). Following scores were assigned: (a) In cases of identical mappings including the cases where the rater did not find a mapping, the agreement score was set to 1; (b) in cases of partial agreement or the case where one rater did not find a mapping but the other did, a score of 0.5 points was assigned; and (c) if

the ratings are completely distinct, 0 points were assigned. Intra- and interrater reliability were defined as the average of these scores.

2.2. Automated Data Mapping Algorithm

Based on the human expert mapping, an algorithm for an automated process for a mapping from LEP to NMDS-AT was defined [12]. NMDS-AT was chosen here as a first step, it is planned to extend the algorithm to G-NMDS later on. This algorithm comprised a five-stage mapping cascade and was implemented using Talend Open Studio (TOS, www.talend.org).

In the first stage, all the cases in which a clear 1:1 mapping between LEP and NMDS-AT was possible, were implemented (LEP→NMDS-AT). In the second stage, medical information (ICD-10 codes of the primary and all secondary diagnoses of the respective patient case) was used to make the mapping decision (LEP + ICD→NMDS-AT). For example, the NMDS category “Care of urinary stoma” will be triggered by LEP “Attending to stoma” and ICD-10 “N00-N99: Diseases of the genitourinary system”, “Z43.5 Attention to cystostomy” or “Z43.6. Attention to other artificial openings of urinary tract”. In the third stage, the nursing information of the remaining cases (all relevant ICNP codes of the patient case) was evaluated to make the mapping decision (LEP + ICNP→NMDS-AT). In the fourth stage, a decision was made if certain combinations of LEP codes, e.g. “Monitoring cuff pressure/tube” together with “Attending to the tracheal cannula” or “Attending to the tracheal catheter” were observed in a given patient case (LEP + LEP'→NMDS-AT). In the last stage, all remaining LEP elements that were not assignable to a corresponding NMDS-AT category were logged as ‘not-mappable’.

2.3. Test Data Set and Automated Mapping

To test the mapping, an anonymized data set comprising 4,390 patient cases from 7 hospital wards (from 6 different special fields) was sampled. This dataset included 789,723 documented LEP interventions (329 different instances of LEP interventions). As this dataset, due to anonymization and other organizational requirements, did not comprise other patient data such as demographic information, ICD diagnoses or ICNP data, a set of 2,000 fictitious test-patients was created. Age, ranging from 0 to 100 years, was randomly assigned and gender proportion was set to 50:50. The 4,390 real, anonymized cases were then randomly assigned to the test-patients. One primary diagnosis from the ICD-10 catalogue was randomly assigned to each case and 3,000 secondary diagnoses, as well as 3,000 ICNP codes, were randomly assigned to all cases. The test cases were stored in a PostgreSQL database for extraction and further processing.

The automated mapping procedures were compiled and exported from TOS as runnable jar files and executed on a MacBook Pro (15-inch, 2017) with 2.9 GHz Intel Core i7 CPU, 16 GB of RAM (2,333MHz LPDDR3) and macOS Mojave. The mapped cases were collected in a separate PostgreSQL database holding the NMDS-AT.

3. Results

3.1. Human Expert Mapping, Intra- & Interrater Reliability

A total of 68.8% (369/536) respectively 71.5% (383/536) instances of *LEP Nursing 3* interventions could be matched to 100% of the NMDS-AT (80/80) and G-NMDS (91/91) nursing interventions.

Table 1 shows the intra- and interrater reliability of the NMDS-AT and G-NMDS mappings. The intra-rater reliability from the NMDS-AT is somewhat higher than that of the G-NMDS (e.g. Intra-rater, Rater 3: NMDS-AT 94.0% > G-NMDS 85.5%). The reason for this may be the lower number of nursing interventions in NMDS-AT (NMDS-AT, n=80 < G-NMDS, n=91). The results of the interrater reliability from mapping round 2 suggest good agreement with 88.4% at the NMDS-AT and 88.3% at the G-NMDS.

Table 1. Average percentage of agreement (%) from the NMDS-AT and the G-NMD in consideration of partial matches (identical mapping = 1; partial mapping = 0.5; distinct mapping = 0) by 3 raters and 2 mapping rounds

	Intra-rater Rater 1	Intra-rater Rater 2	Intra-rater Rater3	Interrater Round 1	Interrater Round 2
NMDS-AT	77.0%	75.3%	94.0%	72.8%	88.4%
G-NMDS	68.0%	80.5%	85.4%	66.8%	88.3%

3.2. Automated Mapping, Outcomes & Performance

The test data set comprised 4,390 real patient cases that had been randomly assigned to 2,000 fictitious patients. The average number of cases per patient was 2.5 (\pm 1.3). Approximately 50 percent of the cases had at least one secondary ICD-10 diagnose (2,355/4,390) respective one ICNP code at least (2,215/4,390).

All *LEP Nursing 3* interventions were aggregated to instances per case and counted. The aggregation resulted in 104,278 distinct interventions for all 4,390 patient cases. Of these cases, 91 percent could be mapped (3,998/4,390) and were found in the NMDS-AT. The number of patients that were mapped to the NMDS-AT was slightly lower at 86 percent (1,729/2,000). The mapping of interventions resulted in a successful match of 47 percent of all instances (49,188/104,278). From these, 98% (48,204/49,188) were mapped in stage 1 (LEP→NMDS-AT). Stage 2 (LEP + ICD→NMDS-AT) accounted for 40 matches, 681 matches were done at stage 3 (LEP + ICNP→NMDS-AT) and stage 4 of the mapping (LEP + LEP'→NMDS-AT) yielded 84 matches.

The execution time of the whole mapping pipeline including data extraction, aggregation, mapping, loading and logging was below one second.

4. Discussion

In our study, we could show that a fully automated mapping process from *LEP Nursing 3* intervention data to elements of an NMDS-AT does work.

The manual expert mapping built a solid base for the implementation of the automated mapping algorithm. However, just under a third of the *LEP Nursing 3* interventions could not be mapped to NMDS elements by the experts. Mostly, these cases were special nursing interventions not covered by the NMDS, such as “Performing acupuncture”, indirect nursing interventions, e.g. “Carrying out surgical hand disinfection”, or nursing interventions, such as “Organising discharge”. Such nursing

interventions without assignment will be reviewed for future developments of the NMDS. The automated mapping performed best in the first stage where direct 1:1 mapping was possible. In the following mapping stages that require additional medical and nursing data the mapping success was suboptimal. This was caused by the fact that sex, age, ICD and ICNP codes had been randomly assigned to the fictitious patients. This shows that the mapping in these stages is very context-specific. With real patient cases and plausible combinations of LEP nursing interventions and medical and other nursing information, we would expect significantly improved mapping results.

5. Conclusion and Outlook

We successfully implemented and tested an automated mapping from LEP to NMDS-AT. We expect that it would be equally successful for mapping LEP to G-NMDS and comparable NMDS. Our approach is not only feasible for mapping LEP to NMDS, but also for other classification systems. All that has to be done is to define the mapping rules by human experts and then to implement the mapping cascade algorithm. Our mapping pipeline supports the transformation of nursing data from EHRs into a minimum data set representation for multiple reuse purposes on a fully automated basis.

Automated Spelling Correction for Clinical Text Mining in Russian

Ksenia BALABAEVA^{a,1}, Anastasia FUNKNER^a and Sergey KOVALCHUK^a

^a*ITMO University, Saint Petersburg, Russia*

Abstract. The main goal of this paper is to develop a spell checker module for clinical text in Russian. The described approach combines string distance measure algorithms with techniques of machine learning embedding methods. Our overall precision is 0.86, lexical precision - 0.975 and error precision is 0.74. We develop spell checker as a part of medical text mining tool regarding the problems of misspelling, negation, experienter and temporality detection.

Keywords. clinical texts, electronic health records, natural language processing, spellchecker, Russian, anamnesis, misspelling correction, word embeddings

1. Introduction

Predictive modeling in medicine and healthcare is developing rapidly, and the quality of modeling results crucially depend on the quality of the input data. In these domains, a significant proportion of the information is presented with texts in natural language. Feature extraction from medical texts is challenging due to the following problems: misprints in medical terms, negation, temporality, and a person (experienter) that have experienced an event (it could be a patient or his or her relative. In the present study, our goal is to develop module of spelling correction to more accurately process and extract knowledge from clinical records in natural language.

2. Related works

Processing of clinical texts in natural language is a well-studied problem, mainly for the English language. There are many tools for labeling text, extracting entities, disease's cases, temporal and negation detection (UMLS, UIMA, IBM Watson, Apache Ruta, etc.), but their require collection of language corpus [1–4]. In some other countries, scientists develop their own corpus-free machine-learning tools or tools that can solve problems which are very specific to their

¹ Corresponding Author, ITMO University, Kronverkskyi prospect, 49, Saint Petersburg, Russia; E-mail: kyubalabaeva@gmail.com.

language [5, 6, 7]. To our knowledge, for the Russian language, a corpus of medical texts has not yet been compiled. There is a small case based on 120 records with labeled diseases and their attributes (complications, severity, treatment, etc.) [8,9]. Machine learning and artificial intelligence are increasingly used in medicine and healthcare. As a result, new methods and models are developed in NLP to obtain additional features from texts [2,4].

To extract knowledge from medical texts it is necessary to cope with many challenges: expansion of acronyms and abbreviations, interpretation of domain specific words, handling spelling mistakes, temporal tagging, negation detection [10,11], etc. There are many solutions for above mentioned problems regarding English language (UMLS, UIMA, OHNLP, etc.). However, NLP instruments for Russian are very limited and there is no generally accepted system to process clinical texts in Russian.

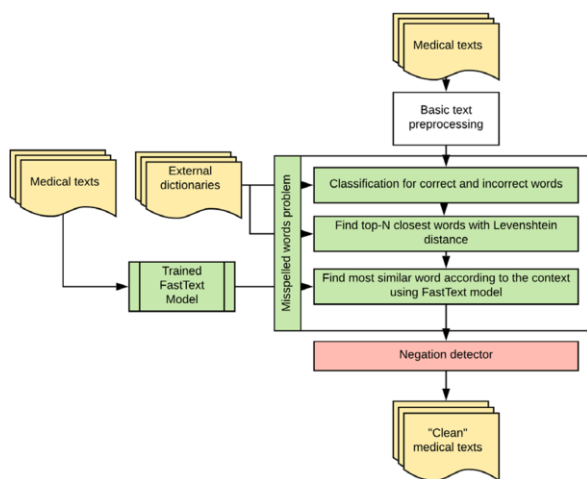

Figure 1. Modules of spelling correction and negation detection. Green blocks indicate methods described in this paper. Pink blocks are developed and implemented by colleagues.

We are developing corpus-independent modules with a spellchecker and a negation detector trained on Russian medical texts. Figure 1 shows the scheme of language processing application. And it also can be used for similar languages. In this research, we used a set of 3434 electronic health records (EHRs) of ACS patients who admitted to Almazov National Medical Research Centre (Almazov Centre) during 2010-2015. EHRs includes disease and life anamnesis, doctor's reports, discharge report, etc. in natural language. Disease anamnesis are the most unstructured records and we used them to demonstrate our approach.

In order to correct misspelled words, we need to solve three main tasks: find incorrect words in text, define the type of mistake and correct the word (Figure 1). To identify misspelled words, we use external dictionaries of russian words, medical terms, drugs, abbreviations, etc. We also broaden the pool with specific non-dictionary words of a high frequency from clinical records. Our module works with the following types of mistakes.

Table 1. Types of misspelled words.

Type of mistake	Incorrect text	Corrected text
Word reduction	anem	anemia
Missing/ misspeled symbols	anmia	anemia
Multiple words separation	hemolyticanemia	hemolytic anemia

In current realization we can automatically identify only multiple words mistake type by dividing the word sequence into all possible subsequences and evaluating if each part is an existing word and their probability to stand next to each other in a sentence is high. The basic idea of correction is to replace the incorrect word with the most similar correct word from the dict. Our approach combines machine learning technics for the word-to-vector representation with more traditional approaches of string distance calculations. To measure the performance of spell checker, we use lexical precision (which is treated as a measure of incorrect words identification), error precision and overall linguistic performance.

3. Method

The classical approaches to measure words similarity is Levenshtein distance or edit distance and its extensions (Damerau-Levenshtein-DL) [13]. It is often used for spell correction [15]. It calculates words similarity according to the minimal number of basic operations required to get the target word from the other. However, this approach doesn't consider the context provided by the sentence.

Figure 2. Most similar words for word 'patient' based on FastText vector representation (on the right). And Most similar words for the word 'diabetes' based on Word2Vec vector representation (on the left)

In order to map words into numerical vectors we use the following word-embeddings: Word2Vec [12] and also FastText [14] on SG and CBOW. We chose Word2Vec and FastText, since they are widely and efficiently used in different NLP problems, including spell correction, and leverage context of the target word. In simple words both methods build a vector representation using a hidden layer of the Neural Network. The difference between models is in token representation: FastText treats each word as a vector of n-grams, whether W2V uses the whole word. Using such representation, we can easily calculate distance

between words with cosine similarity. The example of finding close words is on the Figure 2.

4. Results and discussion

The methods were evaluated on hold-out sample of randomly sampled 200 correct medical words and 200 incorrect medical terms. All results are performed in Table 2. According to the results, we may conclude that both string distance-based algorithms and vector-based methods perform poorly when used separately. Lev. distance and DL distance are lacking context information and the ‘meaning’ of tokens. However, embedding-based approach may confuse correct word for the synonym or other related words. That is why our final model combines these approaches in the following way.

Table 2. Results of spell checker experiments

Method	Lexical Precision	Error Precision	Overall Precision
Levenshtein dist.	0.975	0.52	0.7475
Damerau–Levenshtein (DL) dist	0.975	0.545	0.76
Cos. dist. on Word2vec	0.975	0.42	0.6975
Cos. dist. on FastText CBOW	0.975	0.375	0.675
Cos. dist. on FastText SG	0.975	0.405	0.69
FastText + DL dist	0.975	0.745	0.86
Mean(CBOW, SG, W2V)+DL Dist	0.975	0.745	0.85

At the first stage, we get top-n similar words according to our word-model trained on anamnesis text, then we select m words from the dictionary and top-n words, by minimal DL distance. We also tried different ensembling approaches (voting, bagging, etc.), however it outperformed the others. The error analysis allows us to suggest, that, in general, Levenshtein distance and DL distance when used separately perform better for misprints and the words with missing letters. However, vector-based methods are better at reduced word spelling (anem, anemia). That is why it could be more precise to use independent approaches for each mistake type in future works.

5. Conclusion

We may conclude that in terms of incorrect words detection our approach works steadily and is quite precise 0.975 lexical precision. In terms of error precision it is 0.745, which is high for texts with specialized language, but still there is a room for advancement. The output data can be used for more accurate knowledge extraction from medical texts for the further processing and modelling. In order to improve our approach concerning the problem of spell checking, we are going to expand external dictionaries for more medicine names, rare medical terms,

etc. Also, we want to build ML classifier to separately work with different types of mistakes (Table 1). And our main goal in the future is to expend module's functionality towards negation, experimenter and temporality detection and make a tool for clinical text mining in Russian.

Abstract. Adverse drug reactions (ADRs) are frequent and associated to significant morbidity, mortality and costs. Therefore, their early detection in the hospital context is vital. Automatic tools could be developed taking into account structured and textual data. In this paper, we present the methodology followed for the manual annotation and automatic classification of discharge letters from a tertiary hospital. The results show that ADRs and causal drugs are explicitly mentioned in the discharge letters and that machine learning algorithms are efficient for the automatic detection of documents containing mentions of ADRs.

Keywords. Adverse drug reaction, pharmacovigilance, text mining, document classification, supervised machine learning

1. Introduction

Adverse drug reactions (ADRs) affect 7 to 17% of hospitalized patients [1,2] and can result in serious morbidity, mortality and high costs. They are largely underreported, making active pharmacovigilance useful. The detection of ADRs can be performed through the review of electronic medical records (EMR) [3] or regular ward visits by a trained health professional [4], which can be time-consuming. In this context, data mining techniques, focusing on the automated identification of ADRs from the patient EMR can be helpful [5,6]. These techniques include structured data analysis as well as text mining, including natural language processing (NLP) [7,8]. In this context, techniques for the automatic classification of clinical documents have been proven effective [9–11].

The aim of this study is to assess the feasibility of using NLP techniques to detect the presence or absence of ADRs in discharge letters written in French and extracted from patients hospitalized in a tertiary hospital via a hybrid –machine learning and rule-based– method. In this paper, we will present the supervised learning method. Particularly, three machine learning algorithms for document classification have been applied and evaluated. For the creation of the training and test datasets, manual processing of 300 discharge letters was performed. The results show that ADRs are reported in the documents and that NLP tools are efficient for their automatic detection.

2. Method

2.1. Data collection

Our study was approved by the local ethics committee (study number: 2016-02107). Hospitalized adults for whom a specialized consultation from clinical pharmacologists (in 2015 and 2016) had identified the occurrence of serious ADRs, during or leading to hospitalisation, were included in the study. Out-patients and cases of non-serious ADRs were not included. Based on these criteria, a dataset of 100 positive discharge letters (presence of ADR) and 200 negative letters (absence of ADR) was constituted.

2.2. Data processing

2.2.1. Manual annotation

For the creation of the training and test datasets, an expert manually annotated 100 discharge letters (positive dataset) and validated 200 letters (negative dataset). Based on specific guidelines, sequences of the following categories were annotated:

1. Drugs

The drugs category is divided in 3 sub-categories: a) commercial names, b) international nonproprietary names (INN), c) therapeutic class.

2. ADRs

Occurrences of ADRs and their consequences, symptoms, laboratory values are annotated. ADRs are divided in 3 sub-categories: a) names (*hépatite/hepatitis*), b) periphrases (*perturbation des tests hépatiques/liver test abnormalities*), c) characteristics (*hémoglobine à 75 g/l/haemoglobin at 75 g/l*).

3. Trigger words

Words like *imputabilité/causality*, *stoppé/stopped*, *suspect/suspect* that imply the presence of an ADR are annotated.

4. Drug indications

Indications for drugs entailed in ADRs are annotated.

2.2.2. Automatic classification of discharge letters

For the automatic classification of the discharge letters into positive or negative, a supervised learning approach was followed. The dataset is composed of the positive letters containing at least one annotation of ADR and the negative letters validated by the expert. For this task, three machine learning algorithms widely used for text classification tasks were applied: Support Vector Machine (SVM), Naïve Bayes Classifier, and Linear Classifier. From the whole dataset, 80% was used for training and 20% for testing.

3. Results

3.1. Manual annotation

Out of 100 letters of the positive dataset, 87 letters contained at least one annotated sequence. The mean length of a discharge letter is 785 words. In total, 1471 sequences were annotated. These results are summarized in Table 1:

Table 1. Number of occurrences per annotation category.

Annotation category	Number of occurrences	Unique occurrences
Commercial name	170	76
International nonproprietary name	210	87
Therapeutic class	126	59
Trigger word	293	156
ADR	441	217
Characteristic	130	103
Drug indication	37	28
Periphrasis	64	35

From the 200 discharge letters considered as negative (absence of ADR), 47 reported an ADR and 2 were empty. Therefore, the final negative dataset consists of 151 letters.

3.2. Automatic document classification

Three well-known classification methods implemented in the Scikit-learn python library [12] were applied and compared: Support Vector Machine, Naive-Bayes, and Linear Classifier. For the SVM model, the radial basis function was selected with a ‘scale’ gamma. The Multinomial Naive-Bayes was trained with default parameters. Eventually, the Linear Classifier is based on a stochastic gradient descent with a lower stopping criterion than default (tol=1e-6). Figure 1 represents the classification accuracy of each model after 50 iterations. For each iteration, the test set represents 20% of the whole corpus, i.e. 17 positive documents and 30 negative documents (k-fold = 0.8). The training time is ~100ms for each SVM iteration whereas it takes 2mn for both the Naïve Bayes and the Linear Classifier.

Figure 1. Mean accuracy over 50 iterations.

The SVM classifier achieved 0.83 accuracy, Naïve Bayes achieved 0.94 accuracy and the Linear Classifier 0.94. Complete results are shown in Table 2:

Table 2. Evaluation results of the automatic classification.

Classification method	Class	Precision	Recall	F1 score	Test set
SVM	Positive	0.80	0.97	0.88	17
	Negative	0.92	0.60	0.73	30
Naïves Bayes	Positive	0.93	0.97	0.95	17
	Negative	0.95	0.88	0.91	30
Linear Classifier	Positive	0.97	0.93	0.95	17
	Negative	0.90	0.95	0.92	30

The confusion matrices in Figures 2-4 display the performance of each classifier at the classification task:

Figure 2. SVM.

Figure 3. Naïve Bayes.

Figure 4. Linear Classifier.

4. Discussion

The manual annotation of positive discharge letters by an expert showed that ADRs were explicitly mentioned in most cases (>80%). A significant bias is that the test population were patients who had already received a specialized pharmacology consultation that had identified the ADR, thereafter mentioned in the discharge letter. Drugs were almost equally mentioned as commercial names, INN and therapeutic classes, and this has to be taken into account for their automated detection, especially given the diversity of commercial names in different countries. Trigger words were frequently present (293 occurrences); therefore, they constitute useful tools for the automatic detection of ADRs. ADRs were most frequently mentioned as plain terms, such as MedDRA (Medical Dictionary for Regulatory Activities) derived terms (i.e. *hepatitis*), but were also described as periphrases or as laboratory characteristics in many cases (approximately 200 occurrences) which makes their automatic detection challenging given the fact that the distinction between the 3 sub-categories was not always straightforward even for the human annotator.

For the automatic classification task into positive and negative discharge letters, three machine learning algorithms were applied and evaluated on the dataset. Naïve Bayes and Linear Classifier achieved the same mean accuracy over 50 iterations (0.94) and high precision and recall (Table 2).

A major limitation of this study is that the dataset was manually processed by only one annotator. Also, the classifiers should be applied and evaluated on a larger dataset.

5. Conclusion

In this study, we presented the methodology used for the manual and automatic processing of discharge letters generated in a tertiary hospital in the aim to automatically detect the presence or absence of ADRs. A dataset of 300 discharge letters written in French was manually processed and the output was used to train and test three machine learning algorithms for document classification. After comparison, we concluded that Naïve Bayes and Linear Classifier performed better than SVM at this task.

The manual annotation of the dataset from another expert will serve to create a gold standard corpus. In a next step, the trigger words and sequences describing the presence of ADRs identified during the manual annotation will be included in the rules that are being developed for the automatic identification and extraction of ADRs and their relations with causal drugs. Then, the hybrid method –machine learning and rule-based– will be applied and evaluated on the gold standard dataset.

Automatic Extraction of Risk Factors for Dialysis Patients from Clinical Notes Using Natural Language Processing Techniques

George MICHALOPOULOS^a, Hammad QAZI^a, Alexander WONG^a, Zahid BUTT^a, and Helen CHEN^{a,†}

^a University of Waterloo

Abstract. Studies have shown that mental health and comorbidities such as dementia, diabetes and cardiovascular diseases are risk factors for dialysis patients. Extracting accurate and timely information associated with these risk factors in the patient health records is not only important for dialysis patient management, but also for real-world evidence generation. We presented HERALD, an natural language processing (NLP) system for extracting information related to risk factors of dialysis patients from free-text progress notes in an electronic dialysis patient management system. By converting semi-structured notes into complete sentences before feeding them into the NLP module, the HERALD system was able achieved 99%, 83% and 80% accuracy in identifying dementia, diabetes and infarction, respectively.

Keywords. Natural language processing, Text data mining, Real-world data, Dialysis patient risk factor

1. Introduction

The amount and complexity of data amassed in electronic health records (EHR) are enormous. EHR data are not only a vital part of providing patient care but a rich source for a wide range of secondary uses, including quality control, real world evidence generation and clinical research. Although great progress in the standardization of medical terminology has been made [1], semi-structured or unstructured text data still constitute a large portion of EHR data. Thus, one of the challenges facing real-world evidence generation is the automatic extraction of high quality information from narrative data. However, rapid advances in the field of Natural Language Processing (NLP) could offer viable solutions in extracting information from complex clinical text. NLP toolkits such as cTakes

[2] was capable of recognizing Unified Medical Language System (UMLS) concepts in clinical texts. NLP algorithm was shown to be effective in identifying breast cancer recurrence from clinical notes with above 90% accuracy [3]. Furthermore, Berrios et al.

[4] used a method that involved tokenization, syntactic parsing and noun phrase identification to identify UMLS concepts associated with infectious diseases.

These studies demonstrated the feasibility of using NLP techniques to significantly reduce the work of manual annotation of clinical data. Therefore, the ability to identify

[†] Corresponding Author, Helen Chen, University of Waterloo, School of Public Health and Health Systems; E-mail: helen.chen@uwaterloo.ca

key information such as events of interests and risk factors in the vast amount of narrative EHR data will be increasingly important in personalizing treatment or decision support systems [5].

HERALD is an NLP-based data extraction system, collaboratively developed by a team of clinicians at the Grand River Hospital (Kitchener, Ontario) and researchers of the University of Waterloo.

The HERALD system used the clinical notes of patients in the EHR system to identify relevant information associated with their potential risk associated with withdrawal from the dialysis treatment. More specifically, the EHR data were used to determine whether a patient’s progress notes contain documentation related to dementia, diabetes and infarction [6]. In this paper, we present the design and the validation results of the HERALD system. We demonstrated the feasibility of the HERALD system to process non-standardized narratives of progress notes, as well as semi-structured text ,i.e. templates embedded in the free-text progress notes.

This study provided insights on the utilities and limitations of the open-source NLP toolkit cTakes in processing dialysis content, as well as strategies of adapting the HERALD system to a specific clinical domain.

The study used clinical notes extracted from the renal patient management information system, Nephrocare® from 1st January 2012 to 30th September 2017 in a large tertiary care hospital in Ontario, Canada. The hospital provides a full spectrum of Chronic Kidney Disease services, including nephrology clinics, pre-dialysis, hemodialysis, peritoneal dialysis, home hemodialysis, and pre-transplantation for eligible patients living in Waterloo Region and Wellington County. The Tri-Hospital Research Ethics Board (THREB) and the University Human Research Ethics Committee approved the research project (THREB File # 2016-0619) along with the waiver for “the requirement to obtain patient informed consent”. The notes can be divided into two categories:

(i) **free-text notes**: free text narratives generated by multi-disciplinary care team members (ii) **semi-structured data**: data in a predefined template (e.g., “History of falling; within 3 months [x] NO,[JYES”). Full chart review were performed by three medically trained personnel to extract risk factors associated with dialysis withdrawal. Our study was focused on three specific risk factors: dementia, diabetes and infarction. The statistics for the positive and negative classes for each risk factor can be found in Table 1.

Table 1. statistics of the dataset

risk factor	positive class	negative class
Dementia	39	644
Diabetes	447	236
Infarction	195	488

2. Method

The HERALD system consists of three main modules: **prepossessing** module; **NLP** module and **Rule** module. The process pipeline is depicted in Fig 1.

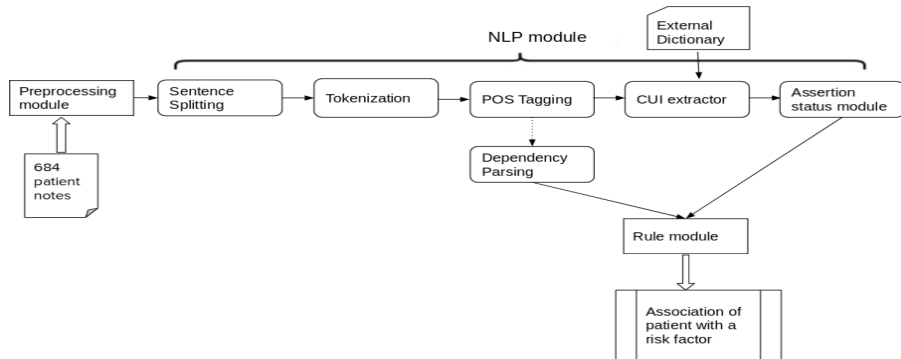

Figure 1. Pipeline of the HERALD system

The function of the **preprocessing** module is to remove the information that was not tagged as correct due to the semi-structured format of the notes. We tracked the number of repetitions of the sentences between the patients and only removed the sentences that were not connected with a filled box and can be observed for multiple patients. The logic behind this policy is that, in structured data, the sentences need to be repeated between the patient forms and cannot change over multiple patients. Therefore, unique sentences are intentionally added by a physician for a specific patient.

For the extraction of information from the unstructured notes, we developed an **NLP** module with the open-source Apache clinical Text Analysis and Knowledge Extraction System (cTakes) [2]. cTakes is a natural language processing tool, whose components are specifically trained for the clinical domain. Our NLP pipeline was composed of (i) A *concept coding* module where we tried to identify terms of interest for which a concept unique identifier (CUI) exists in UMLS [1]. In this module, the sentences were split into tokens and the tokens were normalized to their based form. A POS tagging sub-module was then used to tag the normalized tokens to their part-of-speech and finally a named-entity recognition algorithm used this information to identify terms of interest that exist in the UMLS library. (ii) An *assertion status* annotation module where additional information for each CUI were discovered in the texts, such as whether a term is negated or whether it expresses uncertainty (iii) A *coreference annotation* [7] module which provides information about whether the person of interest for a specific CUI is the patient or a family member or someone irrelevant. Finally, after reviewing the initial results with only the terms from the UMLS dictionary, our expert examined the notes of patients that were flagged as false-negative and he provided new terms that are indicators of a specific risk factor. We created a new custom dictionary with the additional CUI that were determined to be relevant to the identification of different risk factors.

In the **Rule** module, different rules were created in order to determine the existence of a connection between a patient and a specific risk factor. Our first rule was that a patient is diagnosed with a specific risk factor only if all the conditions below were true:

(i) A term/s that was/were connected to this risk factor was found in his notes (ii) The term/s was/were not negated (iii) The term/s did not express uncertainty (iv) The subject of the term/s was/were the patient. Finally, we investigated if a term was connected to the following sentences by using the dependency parser, which was provided by cTakes[8]:

(i) can cause, (ii) risk of, (iii) voicing concerns about, (iv) raising concerns about, (v) no prior history of, and (vi) free. We chose these sentences as they express uncertainty or negation but cTakes failed to identify them. By analyzing the structure of the dependency

tree, our system could understand the terms that were connected to the above sentences and if they were indeed connected to one of them, then we did not consider these terms as proof that a patient is connected to a specific risk factor. Python 3.7 was used for the creation of this module and the preprocessing module.

3. Results

Cardiac disease [9] and dementia [10] were found to be associated with increased risk of death and dialysis withdrawal. Based on the quality of source data, number of patients for each risk factor and the definition of each risk factor, we tested how accurately the HERALD system could determine the connection of dialysis patients with dementia, diabetes, infarction in the progress notes. HERALD processed the notes of each patient in order to identify each risk factor and the results were compared with the manual chart review in order to calculate the classification accuracy. The accuracy of our system was reported in Table 2.

Table 2. Results of experiments

risk factor	Accuracy	Sensitivity	Specificity
Dementia	0.9941	0.8333	1.000
Diabetes	0.8375	0.8318	0.8481
Infarction	0.8038	0.7077	0.8422

4. Discussion

The HERALD system identified a patient with dementia with high sensitivity and good specificity. Given dementia was considered as a contraindication for dialysis treatment, dementia was not as common as other risk factors such as diabetes and infraction in the dialysis population. The HERALD system was able to identify accurately the presence of of dementia in a clinical note, which could help care providers to provide needed support for patients or their families.

One of the limitations of the HERALD system, or any NLP systems in general, is the ability to create generalizable rules that could capture the experience of a medical expert. For example, one false-negative case in our experiment is due to the more complex reasons associated with the inference of the presence of dementia, such as: (i) The patient had delirium (ii) No reversible causes of cognitive and motor decline (iii) Overall history suggestive of dementia. Furthermore, it should be noted that during his chart review, in cases of uncertainty, our medical expert also consulted other clinical reports available in a regional EHR system. These cases were kept as a reminder that, in a real-world scenario, relevant information can be absent from clinical notes and a decision support system should take into consideration multiple sources - structured and unstructured data.

5. Conclusion

Our study demonstrated the feasibility of using an NLP-based system to identify the association of a patient with specific risk factors. This study also proved that the NLP

technique could be a useful tool for identifying passages containing relevant information of interests. However, we also showed that an NLP system could not fully replace the judgment of a clinical expert. Since it is possible to automatically extract structured data from the dialysis program's EHR system (e.g. NephroCare), combining structured data and features extracted from notes, could be a promising future direction to improve the performance of the HERALD system. Also, we aim to combine all available data extracted from the EHR system, including structured and non-structured data in order to build machine learning models to predict if a patient is likely to withdraw from a dialysis treatment. Finally, our future plan is to investigate different feature selection techniques as it is a crucial process for the performance of machine learning models [11].

Acknowledgments

We thank Tina Mah, Kathleen Lavoie, Peter Varga, and Kim Hendrick at the Grand River Hospital for enabling access to data and providing insights on dialysis care. We are grateful for the support of the MITACS and Roche Canada for providing Postdoc Fellowship to Hammad Qazi.

Abstract. Radiology reports describe the findings of a radiologist in an imaging examination, produced for another clinician in order to answer to a clinical indication. Sometimes, the report does not fully answer the question asked, despite guidelines for the radiologist. In this article, a system that controls the quality of reports automatically is described. It notably maps the free text onto MeSH terms and checks if the anatomy and disease terms match in the indication and conclusion of a report. The agreement between manual checks of experienced radiologists and the system is high with automatic checks requiring only a fraction of time. Being able to quality control all reports has the potential to improve report quality and thus limit misunderstandings, loosing time for requesting more information and possibly avoid medical mistakes.

Keywords. Radiology Reports, Quality Control, Text Analysis

1. Background

Radiologists routinely document, report and communicate diagnostic information to the referring clinicians through structured standardized reports (SSRs). Different from unstructured documents, a typical radiology report is divided into the following sections: type of examination, clinical indication, technique, findings and conclusion [1,2]. A referring clinician conveys any identified clinical question requesting a radiology examination. This clinical question is repeated in the *indication* section of a report and the aim of a radiologist is to clearly communicate the answer to this clinical question through the *conclusion* section [3]. Despite guidelines for structuring reports, several problems can prevent clear communication between a radiologist and a clinician. One of the most frequent problems found in reports is a difference between the content of the indication and the conclusion sections whereby a report either fails to answer the clinical question of the referring clinician or has an unclear answer [4]. For example, we identified a report where a clinician requested a MRI (Magnetic Resonance Imaging) scan upon indications of tendinopathy and bursitis

¹ Corresponding Author: E-mail: anjani.dhrangadhariya@hevs.ch.

(comorbidities). The *conclusion* section confirmed tendinopathy but failed to validate or contradict the clinicians’ question about bursitis.

Such human errors could be avoided through automated quality control (Q.C.) of reports. The work of this article describes a Java-based software prototype that employs data integration and semantic comparison to identify the reports with potential differences in reporting and informs the concerned radiologist by flagging them. We assess prototype performance by measuring overall concordance between the indication and conclusion sections using a data set of radiology reports by comparing the results of automated evaluation with human evaluation.

2. Methods

2.1 Data set used

A set of 200 randomly chosen, anonymized, French-language reports was obtained from Institut de Radiologie de Sion (IRS), a private radiology center located in the French speaking part of Switzerland. An individual report comprises the following sections: indications, description and conclusions (see Figure 1).

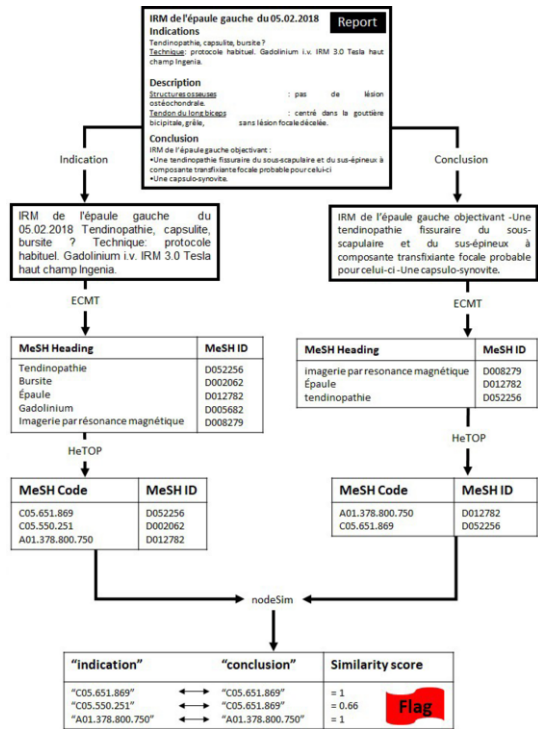

Figure 1. Picture showing the processes followed in the developed prototype.

The data set was not only used to assist prototype development but was also used to evaluate the prototype.

2.2 Medical Subject Headings

Medical Subject Headings (MeSH) are a hierarchically-organized terminology mainly used for organization and cataloguing of the biomedical information and literature. It is organized into a tree structure with its root node branching into 16 broad thematic categories like “Anatomy”, “Diseases”, “Chemical and Drugs”, etc. These categories are further divided into subcategories or MeSH headings. In this way, MeSH enforces uniformity and consistency across the terminology in a way that articles corresponding to a particular topic are indexed under a particular MeSH heading. For example., all the studies about *benign cancer* are indexed under MeSH heading *Neoplasms*². Each MeSH heading in the MeSH tree has a code indicating its location in the tree and a unique MeSH ID [5].

2.3 MeSHSim

MeSHSim is an R-package with “nodeSim” functionality that measures semantic similarity between any two MeSH codes as a function of their length and their position in the MeSH tree. The similarity values range between 0 and 1 [6].

2.4 HeTOP

HeTOP (Health Terminology/Ontology Portal)³ is a portal, housing 70 health terminologies in 32 languages including MeSH and Radiology Lexicon (RadLex). It comprises a semantically interoperable network of 2 million cross-lingual, health-domain related concepts. For example, querying the French term *radiologie* leads to its MeSH counterpart “Radiology” from other multi-lingual terminologies⁴. This rich multilingual content is available for research and can be programmatically accessed via authenticated Representational State Transfer (REST) or Simple Object Access Protocol (SOAP) requests [7].

2.5 ECMT

L'Extracteur de Concepts Multi-Terminologique (ECMT) combines a rule-based and an NLP (Natural Language Processing)-based approach to extract health-related concepts from French-language texts using French-language terminologies in HeTOP. ECMT service can be programmatically accessed via authenticated REST or SOAP requests [7,8].

3. Results

3.1 Prototype developed

The developed prototype fetches a non-empty, radiology report file from internal storage followed by rule-based extraction of free text from the indication and

² <https://meshb.nlm.nih.gov/record/ui?ui=D009369>

³ <https://www.hetop.eu/hetop/fr/?q=&home>

⁴ <https://www.hetop.eu/hetop/#rr=MSH D 011871&oti=all&q=Radiology>

conclusion sections (see Figure 1). An authenticated REST request to ECMT then extracts French-language health-related concepts from the free text. ECMT returns an XML (eXtensible Markup Language) file that is parsed to extract only the MeSH Headings and unique ID's corresponding to Anatomy [A] and Disease [C]. Then, an authenticated REST request to HeTOP returns an XML file with MeSH codes and paths corresponding for the requested MeSH headings. Next, weighted-link semantic similarity between individual anatomy and disease codes is calculated from indication and conclusion using the nodeSim functionality from MeSHSim. If every anatomy and disease code in indication has a similarity score of 0.85 or more with their counterparts in conclusion, the report is considered as

Q.C. passed, otherwise it is flagged. A threshold of 0.85 was chosen, as it pertains to path length three or less between MeSH codes being compared, based on experiments with a few validation cases. This threshold accounts for the conceptual similarity between the MeSH headings being compared. [6]. For example, a similarity score between MeSH anatomy terms “knee” and “toes” is 0.815, but between “toes” and “hallux” it is 0.948.

3.2. Prototype evaluation

To evaluate the performance of the prototype, overall percentage concordance between indication and conclusion for all the radiology reports in the data set was automatically assessed. Out of the 200 reports in the data set, a small subset were flagged by the prototype because the text corresponding to the *conclusion* section was missing in these reports. The *conclusion* text from these reports was deliberately removed for testing this scenario. Of the remaining reports, MeSH terms and codes for the anatomy and diseases were extracted from the indication and conclusion free-texts using ECMT and HeTOP. Only 93 and 143 reports respectively contained MeSH terms corresponding to anatomy and disease. Of these 143 reports, semantic similarity between *indication* and *conclusion* MeSH terms was obtained using nodeSim and total concordance was calculated. To establish a ground truth, two expert radiologists repeated the above procedure manually and calculated the total concordance.

Upon total concordance assessment between the indication and conclusion, the prototype reported 45% concordance for the anatomy information, while manual evaluation reported a 61% concordance. For disease information, the prototype reported 80% concordance versus 88% with the peer review. Based on ground truth, the algorithm accuracy for anatomy was 84% and for disease 92%. It took the experience radiologists about 1.5 hours to conduct manual quality checks, but the prototype did it in a matter of seconds.

4. Discussion and Conclusion

Reports with perfect match for the anatomy and disease MeSH terms between indication and conclusion correctly passed Q.C, multiple reports were flagged when a particular anatomy term (e.g. knee) was mentioned in *indication*, but was missing in the *conclusion*. The prototype success, however, is subject to ability of ECMT to accurately extract the concepts from free texts and also upon availability of a particular concept in the MeSH vocabulary. Currently, the prototype accounts only for the MeSH terminology, which lacks some radiology-specific terms [9]. For example, a report

mentioned *epicondyle* in *indications* section, but not in the *conclusion* section. This report passed Q.C. because no MeSH term corresponding to *epicondyle* was identified from indications. Indeed, this term was absent in MeSH, but present in RadLex⁵ and hence complementing the two can likely improve the results for the missed radiology terms. However, only a part of RadLex is currently available in French. In another instance, a disease term "Déchirure" from free text indication was not identified by the ECMT, but a standardized, English counterpart for "Déchirure" existed in MeSH as "Rupture". This instance was reported to the ECMT team and the term was later added and semantically linked to its MeSH counterpart. Overall prototype performance should also be improved with lexical standardization of disease terms in radiology reports, and further developments in ECMT algorithm.

In conclusion, the automated prototype showed good performance compared to the expert radiologists for assessment of indication and conclusion concordance in the radiology reports. It also reduces time and cost required for the quality control. The prototype additionally identified the lack of systematic reporting of relevant anatomy information in the conclusion sections, a fact that can be highlighted in guidelines for radiologists.

Abstract. Drugs information systems, prescription support softwares, and drug decision support systems need to reason on drug properties. Combined pharmaceutical products need to be considered specifically because they may require a specific processing. Hence, they also need to be identified to automate the population of databases with up-to-date property values. We defined a set of digital filters designed for the identification of antibiotics in a public database. Four different filters are proposed, to be combined to extract the relevant information. Evaluation was conducted to combine filters and retrieve information about random combined antibiotics with success. However, information provided in the structured files of the French drug database is limited; information provided in the HTML files suffers from a lack of quality. Hence, reuse of this data and this information should be performed very cautiously.

Keywords. Drug Combinations, Information Retrieval, Drug databases, Antibiotics

1. Introduction

World Health Organization defines combined drugs as “*pharmaceutical products containing two or more active ingredients (incl. combination packages). Stereoisomeric mixtures are regarded as plain products. Medicinal products which in addition to one active ingredient contain auxiliary substances intended to increase the stability of the product (e.g. vaccines containing small amounts of antibacterials), increase the duration (e.g. depot formulations) and/or increase the absorption (e.g. different solvents in various dermatologicals) are considered as plain products*”. It is assumed that “the classification of combination products is a challenge in any classification system”. For instance, any support decision tool processing dose information should be able to have a

¹ Corresponding Author, E-mail: adrien.ugon@esiee.fr.

specific processing of combined products, and, thus, should be able to distinguish plain to combined medication. These automated tools are used to generate alerts and/or decision or recommendation [1].

Public databases provide information about drugs. French public Drug Database [2] provides information for each drug on the market either in structured Excel files, or as HTML pages including the Summary of Product Characteristics provided by the national drug agency and the medication package insert, provided by the pharmaceutical industry, which markets the medication. These HTML pages can be processed as text documents.

None of the fields of the structured files can be used to decide whether a medication is a combination or not. The world health organization has provided guidelines for combination products, but there is no standard rule that may be used on the basis of the ATC code to identify combined products. ATC Classification system is provided by the World Health Organization to classify active substances in a hierarchy with five different levels [3]. *The system has fourteen main anatomical/pharmacological groups or 1st levels. Each ATC main group is divided into 2nd levels which could be either pharmacological or therapeutic groups. The 3rd and 4th levels are chemical, pharmacological or therapeutic subgroups and the 5th level is the chemical substance. The 2nd, 3rd 5th and 4th levels are often used to identify pharmacological subgroups when that is considered more appropriate than therapeutic or chemical subgroups.*

Drug information retrieval has been investigated in recent years. Adam S. Brown et al. have worked on information retrieval to design a database for drug repositioning [4]. Martin Kralinger et al. have worked on information retrieval for Chemistry, including drugs, using text mining methods [5]. Serkan Ayvaz et al. have worked on information retrieval about drug-drug interaction from publicly available sources [6].

Our paper aims at providing a knowledge-based automated tool to identify combination drugs from information provided onto a public database in the domain of antibiotherapy. Section 2 will describe methods. Results will be presented in section 3 and discussed in section 4.

2. Methods

Our method used to distinguish combined and plain pharmaceutical product uses a bank of successive filters. In our case, four consecutive filters have been designed and implemented.

All pharmaceutical specialties are listed in a file called *CIS bdpm.txt*. Each pharmaceutical specialty is identified by a code called CIS. This file allows to constitute the starting list of products from which we want to extract and isolate combined products. It contains 14 906 specialties.

2.1. Homeopathic medicines filter

According to World Health Organization, homeopathy is a system of medicine born in Europe in the last part of the eighteenth century. In some cases, the dilution is so high that it is almost impossible to find one molecule of the original raw material [7].

By definition, homeopathic medicines may contain several active ingredients. They are referenced, in the Summary of Product Characteristics as homeopathic medicines, or as medicines dedicated to homeopathy. As a consequence, searching for the terms

"homeopathy" or "homeopathic" in the Summary of Product Characteristics HTML pages allows to identify homeopathic medicines.

2.2. Antibiotics filter

Antibiotics are recognized from their "J01" ATC Class. ATC code is given in the Summary of Product Characteristics in HTML pages, which can be obtained by using a regular expression and basic text processing methods. Regular expressions allow to search for a string in a text document by describing their character composition. The ATC code is described as a seven characters string that starts by a capital letter, followed by two numbers, followed by two capital letters followed by two numbers. We observed that some ATC codes used in the HTML pages were misspelled using the O character instead of the 0 number. We integrated this possible misspelling in our regular expression, and used a post-processing step to correct the found ATC Code.

Antibiotics were defined to belong to the "J01" ATC Class. It means that their ATC Code starts with "J01" string.

2.3. Brand vs generic product filter

An interesting information is to be able to distinguish between the brand products and its generics. This information is provided in a text file called *CIS_GENER_bdpm.txt*. Generic groups are defined, identified by a code and a label. For each specialty, identified by a CIS code, the associated generic groups is given; it is also mentioned whether the drug product is an originator brand, a generic, a generic by dosage complementarity, or a substitutable generic. The aim of this filter is to select from a start list of specialties those that are a kind of generic product.

2.4. Single-substance filter

The entire composition of a specialty is listed in a file called *CIS_COMPO_bdpm.txt*. For each specialty, identified by its CIS code, the different pharmaceutical forms are listed separately. For each of them, the whole composition is detailed. Each substance is identified by an identifier, and tagged as *active substance* or *therapeutic fraction*. Indeed, the therapeutic fraction is defined as part of an active substance that carries pharmacological activity. Hence, the dose of the therapeutic fraction is different from the dose of the active substance, and both are provided in the file in two different lines, with a key value allowing to associate corresponding *active substance* and *therapeutic fraction*. If the *therapeutic fraction* is the same as the *active substance*, then only the information about the *active substance* is provided.

The aim of this filter is to remove from the initial list all specialties that have only one *active substance* in their composition. To perform that, therapeutic fractions should not be considered.

3. Results

Our method was evaluated to filter all specialties present in the *CIS_bdpm.txt* file.

Table 1 gives the number of specialties remaining after using each of the filters defined in the previous section. The initial list contained 14 906 specialties. From all there entities, we aim at finding those that are combined products. A chain of combined filters is used for each test; number and percentage of specialties remaining after the filters is provided in the second and third column of the table.

Table 1. Results of the different filters, used separately or combined to each other

Combination of used Filters	Number of remaining specialties	Percentage of removed specialties
Single substance filter	2 245	84.94%
Antibiotics filter	779	94.77 %
Homeopathic medicines filter	14 806	0.67%
Originator brand filter	1 261	91.54%
Single substance + Antibiotics filters	123	99.17 %
Single substance + Homeopathic medicines filters	2 161	85.50%
Single substance + originator brand product filter	176	98.82%
Antibiotics + Homeopathic medicines filters	779	94.77%
Single substance + Antibiotics + homeopathic medicine filters	123	99.17%
Single substance + Antibiotics + homeopathic medicine + originator brand product filters	11	99.93%

As we see, filters can be combined to retrieve the desired drug. From this drug associated characteristics can also be retrieved from the structured text files, like the price, or the reimbursement rate. Natural language processing methods can also be used to retrieve other data like the drug schema, or the contraindications.

4. Discussion

We proposed a method for retrieving combined antibiotic drug based on various filters. The method allows to considerably reduce the number of specialties, and can easily be extended to other types of drugs. Information provided in structured files of the French public drug database is limited, which may prevent from exploiting it in a clinical use purpose. For example, ATC codes, drug schema, contraindications, adverse reactions, excipients, and information about pregnancy and breast feeding are not provided in the structured files. Hence, they should be retrieved from the HTML pages using web connection and natural language processing methods. Web connection is time consuming and makes it very long a mass processing of a database. Natural language processing method are highly dependent of the quality of the data [8].

Moreover, the quality of the HTML pages is also limited. Instead of nesting HTML tags hierarchically, they follow each other in a listed way, making it more difficult to work with section header identifiers. In addition, information may be wrong. For example, we observed that the ATC code was written using the “O” character instead of the “0” number. Once it has been retrieved, it needs to be corrected to be used. For some specialties, the ATC code was absent from the web pages, and it was thus impossible to exploit it to generated and infer other data and information.

Finally, we observed that structured files were inconsistent. For instance, 7 497, i.e. 50.30% of all specialties, were absent of the structured file providing generic groups information. For those specialties, we were not able to infer any result related to the generic groups.

Identifying combined drug products could facilitate the design of decision support systems for alerting drug-drug interactions [9,10].

Abstract. Modern biomedical research is increasingly data-driven. To create the required big datasets, health data needs to be shared or reused, which often leads to privacy challenges. Data anonymization is an important protection method where data is transformed such that privacy guarantees can be provided according to formal models. For applications in practice, anonymization methods need to be integrated into scalable and reliable tools. In this work, we tackle the problem of achieving reliability. Privacy models often involve mathematical definitions using real numbers which are typically approximated using floating-point numbers when implemented as software. We study the effect on the privacy guarantees provided and present a reliable computing framework based on fractional and interval arithmetic for improving the reliability of implementations. Extensive evaluations demonstrate that reliable data anonymization is practical and that it can be achieved with minor impacts on executions times and data utility.

Keywords. data protection, anonymization, reliable computing

1. Introduction

Modern data-driven biomedical research, e.g. in the field of precision medicine which tailors healthcare to the characteristics of individuals, increasingly leverages data science methods such as machine learning [1]. However, when creating the required big datasets, laws and regulations mandate stringent privacy protection. Hence, a wide range of safeguards has to be applied, ranging from organizational to technical measures.

Data anonymization is an important technical building block for implementing privacy protection. In this process, data is transformed in such a manner that formal guarantees, e.g. regarding the risk of singling out, linkage or inference, can be provided. Traditional models of privacy protection such as k -anonymity, ℓ -diversity and t -closeness specify syntactic constraints on output datasets, while more recent models like differential privacy formulate requirements for data processing methods [2].

2. Objective

All methods for implementing privacy models require performing changes to data which inevitably leads to a decrease of its utility. To balance a decrease in privacy risks with a

¹Corresponding Author: Raffael Bild, Institute of Medical Informatics, Statistics and Epidemiology, School of Medicine, Technical University of Munich, Ismaninger Straße 22, 81675 Munich, Germany; E-mail: raffael.bild@tum.de.

decrease of utility, models for quantifying both aspects have been developed. When implementing privacy models in practice, an important challenge lies in the need to reflect their mathematical definitions in software. Privacy models are often formulated over real numbers, which in software are approximated by floating-point numbers with limited precision (typically 64 bits). Computations can therefore yield results that differ significantly from the exact mathematical results [3]. This can make output data of anonymization tools vulnerable to privacy breaches. For example, it has been shown that straightforward implementations of a common method for achieving differential privacy can be exploited to extract the entire content of a (presumably protected) dataset [4]. However, studies of the effects of floating-point errors on the privacy guarantees provided by other methods for data anonymization are still lacking in the literature.

In this article, we aim to fill this gap, with a focus on investigating further methods which are truthful (i.e. non-perturbative) and hence particularly well-suited for the biomedical domain [5]. For this, we discuss the numerical stability of implementations of various privacy models, including k -anonymity, ℓ -diversity, t -closeness and further methods for achieving differential privacy [2]. Moreover, we present a reliable computing framework, which we have integrated into the open source data anonymization tool ARX [6] to mitigate vulnerabilities resulting from the use of floating-point operations.

3. Methods

3.1. Data Anonymization and Floating-Point Arithmetic

Figure 1 shows an example transformation of an input dataset using a combination of generalization (i.e. the replacement of values with more general, but semantically consistent values), suppression (i.e. the removal of values) and aggregation (i.e. the replacement of values with an aggregate, such as their mean). The example output dataset satisfies 2-anonymity, which means that each combination of attribute values appears at least twice (see [2] for further details). Whether or not k -anonymity is satisfied is easy to determine by simply counting the size of groups of indistinguishable records. Implementing other privacy models, such as ℓ -diversity, t -closeness or differential privacy, requires evaluating mathematical expressions over real numbers, though (cf. Section 3.2).

Age	Gender	Height	Age	Gender	Height
23	Male	176	[20-40[Male	179
35	Male	182	[20-40[Male	179
55	Male	176	[40-60[---	169
42	Female	162	[40-60[---	169

Generalization Suppression Aggregation

Figure 1. Example of input data and transformed output data.

In computers, real numbers are typically approximated using floating-point numbers. The number of floating-point values which can be represented with a fixed number of bits (typically 64) is finite. Hence, there exists an infinite number of unrepresentable real numbers. Most implementations of floating-point arithmetic adopt the IEEE standard 754 [7]. It specifies that all floating-point operations have to be performed as if it was possible to perform the corresponding operation with infinite precision, and then to round the result to a representable number. This inevitably introduces rounding errors which add up during sequences of calculations [3].

3.2. Numerical Stability of Common Privacy Models

Implementing some privacy models supported by ARX, e.g. k -anonymity [2], doesn't require decimal numbers at all. Implementing others requires significant amounts of decimal arithmetic, though. Examples are (1) t -closeness which basically requires that the distribution of sensitive attribute values in a set of indistinguishable data records is not too different from the corresponding distribution in the overall dataset or (2) (entropy) ℓ -diversity which requires the distribution (p_1, \dots, p_m) of sensitive attribute values in each group of indistinguishable records to satisfy $-\sum_{i=1}^m p_i \ln(p_i) \geq \ln(\ell)$ [2]. However, by studying possible effects of floating-point error propagation using forward analyses (see e.g. [3] for details), we were able to derive upper bounds for the resulting additive exceedances of the privacy parameters of these models. While a detailed presentation of these analyses is beyond the scope of this article, they showed that the resulting privacy violations are negligible in practice for all syntactic privacy models supported by ARX.

Differential privacy is not a property of a dataset, but a property of a data processing method. It basically guarantees that the probability of any possible output of a probabilistic algorithm does not change “by much” if data of one individual is added to or removed from the input dataset. The Laplacian mechanism and the exponential mechanism are important building blocks for implementing differentially private algorithms [8]. In [9], we have presented a process for implementing k -anonymity while fulfilling (ϵ, δ) -differential privacy. This approach uses random sampling to introduce non-determinism and the exponential mechanism to optimize the utility of output data. Consequently, unlike the majority of differentially private algorithms, it is truthful and therefore well-suited for processing health data [5].

We were able to calculate an upper bound on the rounding error induced by straightforward floating-point implementations of the exponential mechanism. For this, we applied conservative methodologies described e.g. in [3] followed by an extension of the original proof of the privacy guarantees provided [8] which takes rounding errors into account. While a detailed presentation of this analysis is, again, out of the scope of this article, it showed that the additive exceedance of the expected privacy loss ϵ is negligible, with values of about 10^{-10} or less in practical settings.

However, the implementation of differential privacy in ARX requires complex calculations to determine the sampling fraction β and the parameter k for k -anonymity to guarantee the requested degree of privacy protection. Investigating our floating-point implementation, we found that the deviations of ϵ were in the order of 10^{-16} using common values of ϵ (e.g. 0.01, 0.1, 0.5, $\ln(2)$, 0.75, 1, $\ln(3)$, 1.25, 1.5 and 2). The actual values calculated for the parameter δ , however, deviated drastically, as is shown in Table 1.

Table 1. Relative error of δ for $\epsilon = \ln(2)$ using a floating-point implementation.

Requested value of δ	10^{-2}	10^{-3}	10^{-4}	10^{-5}	10^{-8}	10^{-9}
Error of δ [%]	13.3	11.1	17.2	28.4	10.0	27.9

3.3. Design of ARX's Reliable Computing Framework

To solve this problem, we implemented a framework comprising different computing technologies that are reliable, i.e. offer strict guarantees for the accuracy of the calculated results: (1) Arithmetic using exact arbitrary-precision floating-point numbers. This can be used for calculations involving numbers with a finite amount of digits only. (2) Using representations as fractions with arbitrarily long integer enumerators and denominators. This approach can be used to perform exact calculations over rational numbers but it can

become very slow. (3) Interval arithmetic [3], which dynamically computes strict bounds on the errors of mathematical operations. The basic idea is not to operate on (approximations of) real numbers, but rather on intervals which enclose the respective exact real numbers. Functions operating on such intervals yield intervals which are guaranteed to include the exact result. For example, addition can be performed by calculating

$$[x_1, x_2] + [y_1, y_2] = [x_1 + y_1, x_2 + y_2].$$

ARX is implemented in Java and arbitrary prevision arithmetic and fraction arithmetic is well supported by common programming libraries. The number of Java libraries for performing interval arithmetic is, however, known to be limited [10]. Hence, we implemented a basic interval arithmetic framework from scratch while focusing on a minimal amount of easily understandable and verifiable code. We implemented various operators, including the basic arithmetic operators. For more complex functions such as *exp*, *pow*, *log* and *sqrt* we invoke the respective implementations for floating-point values provided by the Java standard library which have clearly defined accuracies. We also implemented various comparison operators such as \leq which allow for reliable comparisons by returning the result of comparing the upper and lower endpoint of their operands. These operators are guarded by checks which raise an error if the relation of their operands is not decidable, i.e. if the intervals are overlapping.

We used the methods and operators provided by this framework to implement the parameter calculation process for differential privacy reliably so that the actual degree of privacy protection provided can be at most more conservative than specified by the user.

4. Results

To evaluate the impact of the reliable parameter calculation on the strictness of the derived parameters we have compared it with a straight-forward floating-point implementation using common values of ϵ ranging from 0.01 to 2 and $\delta = 10^{-i}$ for $i = 1, \dots, 9$.

The differences between the values of β obtained using both implementations were very small with values of about 10^{-16} in all cases. All values obtained for k were identical except for ten configurations using irrational parameters. This is because these numbers have more significant figures than the other values considered, which resulted in higher rounding errors and hence larger intervals during calculations. In these cases, the values of k obtained reliably were (slightly) higher. Using $\epsilon = \ln(3)$, the values of k computed differed for $\delta = 10^{-5}$ and $\delta = 10^{-6}$ ($k = 63$ vs. $k = 66$ and $k = 78$ vs. $k = 82$, respectively). The results obtained when using $\epsilon = \ln(2)$ are listed in Table 2. As can be seen, the absolute differences were at most two. Consequently, for decreasing values of δ , which correspond to increasing degrees of privacy protection, the relative differences between the values of k obtained by both implementations tended to become smaller.

Table 2. Values of k derived from various values of δ and $\epsilon = \ln(2)$.

δ	10^{-1}	10^{-2}	10^{-3}	10^{-4}	10^{-5}	10^{-6}	10^{-7}	10^{-8}	10^{-9}
Floating-Point	7	18	30	42	54	67	81	93	105
Reliable	8	20	32	44	56	68	81	95	107

In contrast to results obtained using the floating-point implementation (cf. Table 1), the actual values of ϵ and δ resulting from reliably calculated parameters k and β were at most more conservative than the privacy parameters specified by the user. In particular, increasing k was necessary to mitigate the violations of δ reported in Table 1. At the same time, the impacts on the intensity of data transformations applied and hence the potential

reductions of data utility are negligible when using recommended parameterizations [9].

We also evaluated the execution times of both implementations on a PC with a quad-core 3.1 GHz CPU, Ubuntu Linux and an Oracle JVM. The results are shown in Figure 2. When decreasing both ϵ and δ (which corresponds to stronger degrees of protection), the relative execution times tended to increase. Using typical values of $\epsilon \approx 1$ and $\delta \approx 10^{-6}$, the execution time of the reliable implementation was about four times higher than the time used by the floating-point implementation. In all experiments with $\epsilon \geq 0.1$, the calculation of parameters terminated in less than one second using both implementations. This contains the range of parameters which is practical for the approach (cf. [9]).

Figure 2. Execution times for deriving β and k from various values of δ and ϵ reliably relative to the floating-point implementation.

5. Conclusion

In this article, we studied how privacy violations resulting from floating-point implementations of anonymization algorithms can be mitigated. We discussed reliability issues resulting from arithmetic operations for a variety of privacy models including k -anonymity, ℓ -diversity and t -closeness as well as an implementation of differential privacy specifically suited for applications to health data [9]. Moreover, we presented a framework comprising reliable computing techniques, including interval and fractional arithmetic. All results have been integrated into the open source tool ARX. Finally, we examined the impacts of the reliable implementation on output data utility as well as execution times and found both to be negligible in practice when realistic parameters are being used.

Blood Lactate Concentration Prediction in Critical Care

Behrooz MAMANDIPOOR^{1 a}, Mahshid MAJD^a, Monica MOZ^{a,b} and Venet OSMANI^a

^a *Fondazione Bruno Kessler Research Institute, Trento, Italy*

^b *Humanitas Research Hospital, Milan, Italy*

Abstract. Blood lactate concentration is a reliable risk indicator of deterioration in critical care requiring frequent blood sampling. However, lactate measurement is an invasive procedure that can increase risk of infections. Yet there is no clinical consensus on the frequency of measurements. In response we investigate whether machine learning algorithms can be used to predict blood lactate concentration from ICU health records. We evaluate the performance of different prediction algorithms using a multi-centre critical care dataset containing 13,464 patients. Furthermore, we analyse impact of missing value handling methods in prediction performance for each algorithm. Our experimental analysis show promising results, establishing a baseline for further investigation into this problem.

Keywords. machine learning, deep learning, clinical decision support, critical care

1. Introduction

Blood lactate concentration is frequently measured in critical care as it is used as an indicator of risk of patients' deterioration. Presence of increased lactate levels is correlated with increased risk of morbidity and mortality. In healthy individuals there is a continuous cycle of lactate production and clearance (metabolised primarily in the liver), while in critically ill patients lactate metabolism is impaired, resulting in elevated lactate concentration. Several clinical conditions have been associated with impaired clearance of lactate, such as liver dysfunction and sepsis. Therefore frequent lactate measurements are necessary to track and assess patients' state. However, lactate concentration cannot be measured without drawing arterial or venous blood, which is an invasive procedure that can increase risk of infections. As a consequence, blood gas analysis may not be ordered as frequently leading to sub optimal rates of lactate measurements [1].

In this respect, there is ample potential for machine learning methods to play a significant role in lactate guided clinical decision making. Such role is especially important when considering that lactate-guided therapy significantly reduced hospital mortality and length of stay as evidenced by several multicentre randomised controlled trials [2,3,4]. However, this potential has not been explored thus far. Addressing the evident need for prediction of blood lactate concentration in ICU, we are the first to compare performance

¹ Corresponding Author: E-mail: bmamandipoor@fbk.eu

of several machine learning methods in lactate concentration prediction. Furthermore, we evaluate several strategies to handle missing values using a dataset of 13,464 patients, containing 12,196,798 clinical records from the eICU critical care database [5]. Our results show that blood lactate concentration prediction could become a useful tool during clinical decision making process in critical care, that may reduce unnecessary blood sampling, while meeting recommendations of Surviving Sepsis Campaign (SSC) on serial lactate testing [6].

2. Methods

We formally define the problem of lactate concentration prediction as follows: For each patient with the set of clinical parameters $S = \{(l, X)_t; t \in T\}$, where l represents blood lactate concentration, X represents the set of all other clinical measures, and t is the time index, we want to predict $l_{t+\beta}$ based on $\hat{S}_t = \{l, \hat{X}\}_{t'} \in [t - \alpha: t]$, where \hat{X} is the selected set of clinically relevant measurements out of X . Therefore, we formulate a regression problem using Eq.(1).

$$f: \hat{S}_t \rightarrow l_{t+\beta}, \min_{\theta} \text{Loss}(f(\hat{S}_t, \theta), l_{t+\beta}) \quad (1)$$

In other words, the objective of lactate prediction is to predict the blood lactate concentration of a patient in the next β hours using a selected set of their measurements taken in the past α hours.

For our work we use eICU Collaborative Research Database [5], a multi-center intensive care unit database with high granularity data. The eICU database comprises 200,859 patient unit encounters for 139,367 unique patients admitted between 2014 and 2015 to hospitals located throughout the US. The final patient cohort contained 13,464 patients (14,477 ICU stays) with 12,196,798 clinical records, where we grouped these records into 2 hour windows. Patient's mean age was 61.8 ± 15.7 years (45% female). For our case study, the relevant clinical features for the selected cohort are chosen based on advice from the clinician and outlined in Table 1.

Critical care data suffers from several limitations with missing data as one of the main challenges. In the eICU dataset, the percentage of missingness per feature is between 0 to 96 which needs to be addressed properly. Addressing missing values is typically dependent on the cause of missingness. Statistically speaking, there are three types of missing values: missing completely at random (MCAR) which happens on an unrelated cause, missing at random (MAR) which implies a relation between missing value and other present values, and missing not at random (MNAR) which implies a relationship between the value of the variable and its missingness [7]. On the other hand, there are several imputation methods to handle missingness. Mean and forward imputations are basic single-value imputation methods, which only consider the information in the past values of the variable and work best under MCAR assumption. Multiple imputation [8], Matrix Factorisation [9], PCA [10], SoftImpute [11] and Random Forest [12] are the most known traditional machine learning methods that find the substitute for missing values based on the relation between observed and missing features. These methods perform best when handling MAR cases. Finally, MNAR cases are the hardest to manage. A helpful solution to capture the information behind missingness of variables is to use missing

indicators. These indicators can either be used directly aside data or inside the prediction model structure. Note that indicators can also be useful in MAR and MCAR, since they differentiate the imputed values from the observed ones and the prediction method can use this information to ignore bad imputations.

There are a vast number of successful regression methods used for healthcare data which could be grouped into three categories: the statistical regression methods, the traditional machine learning methods and the rising deep learning methods. Here we investigate one method from each category: Lasso regression(LR) as linear regression, to benefit from its feature selection capabilities, Random Forest(RF) as nonlinear model with an ensemble of decision trees, and Long Short-term Memory(LSTM) as temporal deep learning model to learn complex temporal relation in data.

3. Results

Data preparation. Data is preprocessed in six steps. (1) Patient cohort is selected based on three inclusion criteria; adult patients (age > 18), with at least two measured lactate levels, and with at least 18 hours length of stay in ICU. (2) The relevant variables are selected based on advice from the clinician. For our case study, the relevant clinical features for the selected cohort are outlined in Table 1. A detailed description of each variable is provided in the original eICU paper [5]. (3) Some features exist in more than one table under different names. These features are aligned to a unique feature in time. (4) The selected data is aligned in time since each feature is measured in an arbitrary time and frequency. We resampled time-series data into regularly aligned periods where each feature is sampled every 2 hours. In case a feature is measured more than once during each two hour interval, the last record is used. (5) Noise and outliers are addressed as follows: for each feature, the valid interval is defined based on clinical knowledge and the values out of the valid scope are considered as missing values. (6) The data is split into training and testing parts, which is done using five-fold cross validation where at each fold 80% of the data is considered as training and the rest is test data.

Settings. All the imputation methods are applied using python based on

fancyimpute, predictive imputer, and sklearn open-source libraries. Also for all the machine learning methods, the default parameters proposed by their authors are used. The LSTM network has 2 layers of 1024 units with *Glorot* normalisation and *tanh* activation, each followed by a drop out layer of 0.6. Adam optimizer is used with learning rate starting from 0.0001 and the model is trained for 20 epochs with batch size 100. To ease LSTM convergence, data is normalised to have zero mean and a standard deviation of one. The LSTM model is implemented using Keras and Tensorflow as backend and one GTX 2080 Ti as GPU.

All combinations of introduced prediction models and imputation methods are examined on eICU data and their results are reported in Table 2. To measure the quality of imputation methods regarding lactate prediction while preserving the structure of data, we report Mean Absolute Error (MAE), Root Mean Squared Error (RMSE), and R-squared (R^2) as indicators of the predictive performance of the regression models. The mean and standard deviation of each measure on five fold cross-validation of data is reported. The best results are shown in bold. As the results suggest, both regression model and imputation method affect the prediction results. LSTM performed significantly better compared to LR an RF using the same imputation method. Therefore, it can be concluded that the data contains complex relations not only between measurements but also across their values in time that were captured by the LSTM model.

Table 2. The results of all combinations of prediction models and imputation methods. The mean and standard deviation of various metrics on five fold cross validation of data is provided. MAE, RMSE, and R^2 stand for Mean Absolute Error, Root Mean Squared Error, and R-squared respectively. LR, RF, and LSTM stand for Linear Regression, Random Forest, and Long Short Term Memory.

Measure	Regression Imputation		LR	RF	LSTM

4. Conclusion

Considering the importance of monitoring blood lactate levels, the ability to predict blood lactate concentration may provide clinicians sufficient time to devise interventions for rapidly deteriorating patients. At the same time it may decrease the frequency (and the associated cost) of invasive lactate measurements in stable patients. Therefore, we defined the problem of lactate prediction from ICU data in details and offered solutions with well-known prediction and imputation methods.

Our results show that LSTM-based method can predict lactate level with a Mean Absolute Error of 0.665 across 13,464 patients from different hospitals and ICU units. Furthermore, we show that indicator imputation method achieves highest performance in our dataset, suggesting that a missing value indicator is informational and increases predictive power over other, mean-based imputation methods. Future work will investigate prediction of lactate levels in patient sub-populations and its impact on critical care at patient as well as organisational level.

This work was partially supported by the European Union's Horizon 2020 research and innovation program under grant agreement #769765.

Abstract. The present work provides a real-world case of the connection process of a hospital, 12 de Octubre University Hospital in Spain, to the TriNetX research network, transforming a compilation of disparate sources into a single harmonized repository which is automatically refreshed every day. It describes the different integration phases: terminology core datasets, specialized sources and eventually automatic refreshment. It also explains the work performed on semantic normalization of the involved clinical terminologies; as well as the resulting benefits the InSite platform services have enabled in the form of research opportunities for the hospital.

Keywords. I2B2, ICD, LOINC, ATC, SNOMED-CT, Clinical research, Secondary use of EHR, Semantic interoperability, Clinical data integration.

1. Introduction

The adoption of Electronic Health Record (EHR) systems for storing clinical data has been trending upwards in the last decades, especially in larger hospitals where record tracking has become increasingly difficult as they grow. However, the formats used by each department or area for recording and storing these data are rarely consistent. The process of extracting and combining information from several sources within a hospital in order to, for instance, allow observational studies on broad cohorts of patients, can be anything but trivial.

This scenario is where resources such as the InSite platform [1] come into play. InSite is a secure service platform which enables healthcare organizations across Europe to harmonize their clinical data sources in order to increase data availability and its efficient reuse for research. InSite, as the European branch of TriNetX [2], has helped establish a global Clinical Research Network, with over 130 healthcare providers across 23 countries and almost 4.200 clinical trial opportunities already delivered.

When a new hospital joins the network, InSite integrates its clinical sources to a local node, an I2B2 [3] repository where all this data is homogenized, which is linked to the central InSite platform. Other common data models such as OMOP or PCORnet could have been chosen as well, but I2B2 was selected for being a flexible and widely used standard [4, 5, 6]. Federated analytics technology ensures that patient data never

leaves the hospital and remains under local control, while providing aggregated results to research questions.

The present paper provides a real example of the complete connection process of 12 de Octubre University Hospital [7] in Spain to the InSite network, transforming a compilation of disparate sources into a single harmonized repository which is automatically refreshed on a daily basis.

2. Methods

During the data loading process for new hospitals, integration is not performed simultaneously for all sources. It is divided in iterations or phases: a historical data load, integration of specialized sources and lastly automation of incremental updates.

In the case of 12 de Octubre, the complete process required around 2 years of work, starting April 2017. Details on the specific steps taken and data sources involved in each of the phases are presented below.

2.1. Phase I – Minimum Basic Data Set (MBDS)

The initial phase consisted on a historical data load of the essential domains from the EHR system of the hospital (HP-HCIS, [8]). This includes Demographics (age, gender and vital status related data), Providers (e.g. physicians, nurses, etc.), Visits (any clinical transaction generating a set of data), Diagnoses, Procedures, Laboratory tests and Medication. This data was extracted from the source database and transformed, directly through series of queries, to fit the I2B2 structure of its target table.

When local coding systems do not match the reference terminologies used in InSite, specific mappings have to be developed and loaded into the hospital's I2B2 node in this step. The mapping effort to standard clinical terminologies has been performed by a multidisciplinary team from both 12 de Octubre and InSite.

For diagnoses and procedures, the hospital had generated mappings from their local coding to ICD9CM [9] or, for recent data, to ICD10CM and ICD10PCS [10]. In the interest of a joint exploitation of both historical and recent information in a single terminology, codes stored in ICD9CM were also mapped to ICD10CM or PCS respectively by InSite, using internally developed mappings to increase reliability and maintain legacy data [11, 12].

Translation of most local laboratory tests into LOINC [13] was provided by the hospital. For those local codes not present in the hospital's internal mapping, InSite developed a manual mapping to LOINC.

Finally, for medication data, AEMPS (*Spanish Agency of Medicines and Medical Devices*) codes were translated to ATC [14] using the official mapping [15], which was further refined by 12 de Octubre.

2.2. Phase II – Specialized Sources & Expansion of Previous Data

The second phase involved two main extensions of the harmonized data. Firstly, the integration of four new sources: cancer registry, anatomic pathology, clinical findings and oncological medication. Secondly, an update of the preexisting sources and the inclusion their additional visit types: inpatients, outpatients, ambulatory surgery or

emergency room. Two of the new sources were processed through exports of their original systems instead of direct database connections. These export files were then integrated with the rest of the collected information.

Regarding the terminologies assigned to the new sources, cancer registry and anatomic pathology data had been coded using a local terminology. Before entering the I2B2 repository, all topology and most morphology information was mapped by InSite to ICD-O-3 [16] while the remaining morphology information, together with specific cancer registry concepts such as TNM staging data, were mapped to SNOMED-CT [17].

Clinical findings data, similarly to what had been done for laboratory tests in phase I, was mapped automatically to SNOMED-CT through the hospital’s internal mapping tables before extraction. Oncological Medication was locally already in ATC.

2.3. Phase III – Data Load Automation

The first step taken during this phase of the integration process was to perform a load from all data sources in order to bring historical data completely up to date, bridging the time gap since the latest manual refreshment. This was followed by the introduction of automatic incremental updates, which begun by the implementation of HL7 (*Health Level 7*, [18]) channels for ingesting fresh data from the different sources.

The new loading process entails a two-step ETL. Whenever fresh data is recorded, individual HL7 messages are sent through a channel implemented by the hospital, connected to the source systems. Subsequently, these messages are processed in a channel implemented by InSite, which models the information in the format required by the I2B2 repository.

After each channel has been implemented, InSite continues to provide technical support and validation tasks as requested by the hospital to ensure its stability, such as filtering of duplicate messages, detection of empty fields or local unit errors.

There are currently eight channels ingesting messages periodically from the following data domains: diagnoses, procedures, laboratory tests, medication, oncology and clinical findings. These incremental updates occur daily. Fresh data extraction requires an average of 10 minutes, after which the steps of processing, quality checking and load take place. The I2B2 repository and InSite applications for the hospital’s internal use remain accessible at all times during this process.

3. Results

Tables 1 and 2 summarize the outcome of the integration process for phases I and II.

Table 1. Details on the historical data load of the Minimum Basic Data Set (MDBS) – Phase I.

Data domain	Visit type	Period	# Records	Target I2B2 Table
Demographics	Inpatients	–	2.672.821	PATIENT_DIMENSION
Providers	–	–	43.053	PROVIDER_DIMENSION
Visits	Inpatients	01/1999 - 02/2017	22.462.945	VISIT_DIMENSION
Diagnoses	Inpatients	01/2010 - 02/2017	1.990.697	OBSERVATION_FACT
Procedures	Inpatients	01/2010 - 02/2017	1.036.653	OBSERVATION_FACT
Laboratory tests	All	01/2016 - 02/2017	148.761.307	OBSERVATION_FACT
Medication	Inpatients	01/2011 - 02/2017	1.996.671	OBSERVATION_FACT

Table 2. Details on the load of specialized sources and additional visit types – Phase II. Visit types include Inpatients (IN), Outpatients (OUT), Ambulatory Surgery (SUR) and Emergency Room.

Data domain	Visit type	Period	# Records	Target I2B2 Table
Demographics	All	–	2.698.508	PATIENT_DIMENSION
Providers	–	–	43.700	PROVIDER_DIMENSION
Visits	–	01/1999 - 07/2017	23.579.551	VISIT_DIMENSION
Diagnoses	IN,OUT,SUR	01/2010 - 07/2017	3.142.581	OBSERVATION_FACT
Procedures	IN,SUR	01/2010 - 07/2017	1.730.628	OBSERVATION_FACT

Medication	IN,OUT,SUR	01/2008 - 07/2017	2.371.452	OBSERVATION_FACT
Cancer registry	All	01/1980 - 07/2017	66.966	OBSERVATION_FACT
Anat. pathology	All	01/2014 - 07/2017	783.894	OBSERVATION_FACT
Clinical find.	All	01/2010 - 07/2017	11.492.325	OBSERVATION_FACT
Oncology med.	All	01/2002 - 07/2018	252.267	OBSERVATION_FACT

After the implementation of incremental updates during phase III, the volume of harmonized data has continued to grow as fresh information is automatically included in the repository. Figure 1 illustrates the evolution of the volume per data domain over the integration process.

Figure 1. Snapshot of the data volume per domain through the different phases of the integration process.

Quality assurance processes were undertaken in parallel to the described ETL processes and a number of expected fluctuations have been identified in collaboration with the hospital’s IT team. As a future line of work, time series analyses of volume variations in the different data domains are being designed, in order to extract patterns of data peaks and drops, and to forecast its evolution for detecting unexpected variations.

As an example of this evolution of data volume over time, figure 2 shows the number of new laboratory records loaded per month in the period of January 2015 to August 2019. Indicator 1 marks the moment in which the hospital’s coding team implemented a filter to remove redundant laboratory records, thus reducing the mean monthly volume of new data. The second indicator marks the period in which laboratory data load migrated to the appropriate HL7 channel and automatic updating of this source began.

Figure 2. Monthly evolution of laboratory data. Grey: manually loaded. Black, dashed: with automatic updates.

4. Conclusions

The InSite team, in collaboration with the IT department of 12 de Octubre University hospital, have managed to integrate a number of heterogeneous, dissociated clinical data sources into a single, harmonized repository where information is refreshed daily, without manual intervention, on a record-to-record basis. Not only does this help the hospital's physicians access patient information from several data domains easily and efficiently, but thanks to incremental updates it also allows the hospital to perform clinical trial recruitment protocols with the least possible data availability delay. Keeping harmonized data up to date implies physicians can look for suitable patients including those currently under treatment.

Apart from the numerous clinical trial opportunities offered through the InSite platform, joining the network has enabled the participation of 12 de Octubre in a number of European research projects in collaboration with prominent healthcare and research institutions, including EHR2EDC[19], ECRIN[20], RIS[21], CDISC[22] or ICHOM[23].

Regarding future courses of action, complementary clinical information sources are continuously being identified and integrated within the hospitals of the InSite network. In the case of 12 de Octubre, new data sources currently considered are microbiology, genetics, HIV registry, medication posology and specialized parameters from breast and lung cancer. Further iterations of integration will provide essential data to drive the current clinical research more efficiently.

Character-Level Neural Language Modelling in the Clinical Domain

Markus KREUZTHALER^{a,b,1}, Michel OLEYNIK^a and Stefan SCHULZ^a

^a*Institute for Medical Informatics, Statistics and Documentation,
Medical University of Graz*

Abstract. Word embeddings have become the predominant representation scheme on a token-level for various clinical natural language processing (NLP) tasks. More recently, character-level neural language models, exploiting recurrent neural networks, have again received attention, because they achieved similar performance against various NLP benchmarks. We investigated to what extent character-based language models can be applied to the clinical domain and whether they are able to capture reasonable lexical semantics using this maximally fine-grained representation scheme. We trained a long short-term memory network on an excerpt from a table of de-identified 50-character long problem list entries in German, each of which assigned to an ICD-10 code. We modelled the task as a time series of one-hot encoded single character inputs. After the training phase we accessed the top 10 most similar character-induced word embeddings related to a clinical concept via a nearest neighbour search and evaluated the expected interconnected semantics. Results showed that traceable semantics were captured on a syntactic level above single characters, addressing the idiosyncratic nature of clinical language. The results support recent work on general language modelling that raised the question whether token-based representation schemes are still necessary for specific NLP tasks.

Keywords. Neural Networks, Electronic Health Records, Natural Language Processing

1. Introduction and Motivation

So-called word embeddings have become popular for various natural language processing (NLP) tasks. They capture the semantics of a word to a certain degree and have replaced term-weighted vector-based representation schemes from the pre-deep learning era. For building such embeddings, a critical amount of textual data is needed to obtain stable vector representations with different surrounding contexts. The excellent performance of such representations, in combination with different neural network architectures were demonstrated in various clinical NLP tasks.

In most cases, character-based input representations were handled as a merely supportive information layer for word-level embeddings in different NLP problem domains.

¹Corresponding Author: Institute for Medical Informatics, Statistics and Documentation, Graz General Hospital and University Clinics, Auenbruggerplatz 2, 8036 Graz, Austria, Europe; CBmed GmbH — Center for Biomarker Research in Medicine; E-mail: markus.kreuzthaler@medunigraz.at.

The idea that character-level neural language models (CNLM) alone, based on recurrent neural networks (RNN) and more specifically long short-term memories (LSTM) are able to sufficiently capture the information needed for a given task recently got again attention by various research groups. The main motivation behind these experiments — Google named them “tokenizer-free language models” [1] — is to address NLP tasks using only single characters as input representations, thus capturing human language on its most granular representation level [2].

In this work we investigated the possibility of character-based *clinical* language modelling in order to address its well-known idiosyncrasies (telegram-style, single-word composition, spelling variants, and typing errors) with the purpose of optimally capturing the meaning of real-world textual data.

The paper is structured as follows: Section 2 gives an overview of recent work on CNLMs. Section 3 describes the clinical data set for the investigation as well as used methods and language models. Section 4 exemplifies the results, gives insight into the lexical semantics of the obtained embeddings and discusses the results. Finally, Section 5 concludes the paper and provides an outlook for further investigation.

2. Background and Related Work

Zhang and LeCun [3] applied convolutional neural networks (CNN) on a single character input level for ontology classification, sentiment analysis and text categorization. They stacked six convolutional layers and three fully-connected layers for the specific tasks. The experimental design reached a test set based accuracy of 0.98 for ontology classification (DBpedia), 0.95 for sentiment analysis using the Amazon review polarity data set, and 0.60 exploiting the Amazon review full score data set. An accuracy of 0.71 was reached for the Yahoo! Answers topic classification data set.

Kim et al. [4] applied single character-level inputs to a deep neural network model consisting of a CNN, a highway network over characters, and an LSTM at the end. They tested their model on the Penn Treebank for different languages and achieved state-of-the-art results with less parameters in comparison to the other machine learning based approaches. They reported a perplexity of 78.9 on the English Penn Treebank test set. Their character-level input models outperformed word/morpheme-based input representation schemes in general. The model was also shown to be able to capture different levels of semantics on a token level constituted by a time-series based input representation scheme of single characters.

More recently, Choe et al. [1] from Google showed that tokenizer-free CNLMs are competitive with current state-of-the-art language models using the One Billion Word benchmark in combination with a deep transformer neural network containing 40 self-attention layers. By using several semantic benchmarks, they showed the ability of their network to capture layer-wise word-level semantics even though the input representation was character-based. This work corroborates another recent work from Stanford and Facebook [5], which concluded that CNLMs based on recurrent neural networks (e.g. LSTMs) are able to capture upper-level semantics.

Motivated by the research mentioned above, we explored to what degree CNLMs can capture token-level lexical semantics from clinical texts. We accomplished that by fetching embeddings out of an RNN, after training it on a critical mass of real-world data,

viz. ICD-10 coded problem list entries from a clinical information system, modelled as a time series of one-hot encoded single characters. With a nearest neighbour search on selected clinical narrative content we fetched word types within the embedding space and hypothesized that they were semantically connected to the given input. To the best of our knowledge, this is the first investigation on the extent of CNLM-based lexical semantics that can be obtained from clinical narratives.

3. Methods and Data

The initial data set is composed of ~ 1.9 million unique 50 characters long problem list descriptions in German, annotated with ICD codes. These annotations had been done by physicians on in-patient discharge, the ICD codes being relevant for billing. To have a sufficient number of initial samples per class we took the top-100 most frequent three-character ICD-10 codes from a 90% split and up-sampled them to the most common one to balance the whole data set. The final data consisted of ~ 6 million coded problem list entries used for CNLM training downstreamed to their corresponding disease code.

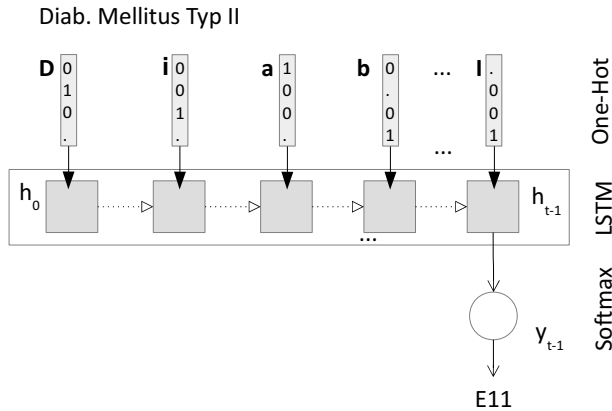

Figure 1. Schematic description of the LSTM network in use [6].

After having prepared the training data set, we fed it to an LSTM network as depicted in Figure 1. The problem list entry is represented as a series of one-hot encoded input vectors of dimensionality 122 (number of alphabetic characters in the training corpus) to the recurrent neural network. We refrained from any pre-processing and used all strings as they were in the raw data. The neural network was trained for 5 epochs (~ 73 hours) using the `deeplearning4j`² framework on an NVIDIA Titan V GPU with the following parameters: mini-batch size: 512; learning rate: 1.0; L2 regularisation: $1E-6$; weight initialisation: XAVIER; updater: RmsProp; LSTM hidden state vector size: 128; number of LSTM cells: 60; LSTM activation: TANH; output layer activation: SOFTMAX; output layer loss function: MCXENT; total number of network parameters: 141,412, which is about a factor of 40 less than available training observations.

²<https://deeplearning4j.org/>

In order to obtain a specific character-induced word embedding, we accessed the hidden state h_{t-1} out of the cell at step $t - 1$ for a given token \mathbf{X} of length t . Using the k-d tree data structure we built a searchable $k = 128$ dimensional index for all occurring types in the training corpus to get back the *top n* nearest neighbours given an input vector. The input vector was inferred the same way using the trained LSTM network as described before. With the trained LSTM network and the k-d tree data structure, we could obtain the nearest neighbours in reasonable time by exploiting the cosine similarity measure in the embedding space. This space was used to test our hypothesis that nearest neighbours to a given input vector contain verifiable semantics with respect to the initial search vector.

4. Results and Discussion

Table 1 lists the top 10 nearest neighbours to a given concept in descending order. The first column contains the results for the disorder “Nikotinabusus” (nicotine abuse). Interestingly, most of the nearest embeddings to the given token contain variations of the clinical quantification of smoking cigarettes in pack years (py), a level of detail that is irrelevant for ICD. The pack year (py) is the unit in which the inhaled smoke dose of a cigarette smoker is approximately described. Moreover, the quantitative values correspond to the manifestation of a harmful use of nicotine via some smoking behaviour.

“Nikotinabusus”		“Handverletzung”	
Word type	Sim.	Word type	Sim.
chronisch	1.00	Handverletzung	1.00
(15/die)	0.99	Strecksehnendurchtr	0.91
abuse	0.99	Fingernagelbruch	0.81
(20Stk./d)	0.99	Zeigefingergrundgliedfraktur	0.80
(25/d)	0.99	ausw.kons.	0.80
Z/d)	0.99	Handwurzelkontusion	0.79
(135	0.99	eingestauchte	0.79
(Abstin.seit	0.98	Daumenendphalanxstauchungsfraktur	0.78
(30pys)	0.98	Handwurzelknochen-Fraktur	0.78
(50pj)	0.98	4.links	0.77

Table 1. Top 10 nearest neighbors with corresponding similarity scores for two example words.

The second column contains the most similar character-level-induced word embeddings for “Handverletzung” (hand injury). The majority of the top 10 results contain different types of injuries of the body structure hand, and anatomical locations which are part of the hand. A remarkable result is the semantic response “Daumenendphalanxstauchungsfraktur” (thumb end phalanx compression fracture). Semantically obviously related to each other, the lexical representation of “Handverletzung” and “Daumenendphalanxstauchungsfraktur” has nearly nothing in common with a Levenshtein distance of 25.

5. Conclusion and Outlook

In this paper we investigated to what extent a CNLM with an LSTM network architecture is able to induce meaningful lexical semantics in the clinical domain. We trained the network on ~ 6 million ICD-10 coded problem lists, a critical amount of training data for language modelling. After the training, we fetched the embeddings by accessing the hidden state h_{t-1} within the cell at the last step of an input word of the LSTM network. We then indexed the resulting 128-dimensional character-level-induced word embeddings using a k-d tree data structure and, via a top 10 nearest neighbour search, obtained the most similar whitespace separated tokens given an input word. We showed that meaningful lexical semantics could be captured at this representation level using an exploratory evaluation.

Our results support recent investigations that single character-level representations to RNNs are able to fetch semantics in contrast to the most low-level fine-granular input scheme. The work presented here uses a single LSTM network in contrast to more complex models from recent research on deep transformer models like BERT [7] or stacked Bi-LSTMs like ELMo [8] for contextual embedding modelling.

Furthermore, this preliminary evaluation was done purely on a human interpretation level on selected examples. Future investigations of CNLMs in the clinical domain should consider objective evaluation measurements for semantic similarity and language model quality. Besides the mentioned limitations, the work presented in this paper supports the promising potential of CNLMs in processing raw clinical language in a robust but nevertheless semantically precise manner.

Clinical Abbreviation Disambiguation Using Deep Contextualized Representation

Mingkai PENG^{a,1} and Hude QUAN^a

^a*Department of Community Health Sciences, University of Calgary, Calgary, Canada*

Abstract. The objective of this study is to develop a method for clinical abbreviation disambiguation using deep contextualized representation and cluster analysis. We employed the pre-trained BioELMo language model to generate the contextualized word vector for abbreviations within each instance. Then principal component analysis was conducted on word vectors to reduce the dimension. K-Means cluster analysis was conducted for each abbreviation and the sense for a cluster was assigned based on the majority vote of annotations. Our method achieved an average accuracy of around 95% in 74 abbreviations. Simulation showed that each cluster required the annotation of 5 samples to determine its sense.

Keywords. clinical abbreviations, deep contextualized representation, cluster analysis

1. Introduction

Abbreviations are ubiquitous in clinical notes as they are a convenient way for health care providers to record clinical concepts such as diseases and procedures within limited time. However, ambiguity of clinical abbreviations is very common. It was reported that 33.1% of abbreviations in the Unified Medical Language Systems (UMLS) have more than one sense[1]. Abbreviation disambiguation is the process of identifying the correct sense of an abbreviation within a given context and is an important step to automate information extraction from clinical notes. Understanding clinical abbreviations still remains a challenging task for current clinical natural language processing (NLP) systems due to two major reasons: lack of a complete sense inventory of abbreviations, and efficient methods to disambiguate abbreviations with multiple senses[2].

Overall, supervised learning performs well in clinical abbreviation disambiguation[3]. These methods usually build a classifier for each abbreviation using an annotated corpus with a large number of instances. However, the annotation process to create training data is expensive and time-consuming, which limits the scalability of supervised learning approaches. Many studies have explored different ways to reduce the annotation efforts for abbreviation disambiguation. Semi-supervised approaches have been explored to generate training data by submitting the long forms with their corresponding abbreviations and then training a classifier on the generated data[3]. The semi-supervised approach can achieve up to 90% of classification accuracy. To build the sense inventory, instances of an abbreviation were clustered into different sense clusters

¹ Corresponding Author, 2500 University Drive NW, University of Calgary, Calgary, Canada; E-mail: mpeng@ucalgary.ca.

and selected instances from each cluster were manually annotated to create the final list of senses[4]. The clustering-based method significantly reduced the annotation cost and increased the sense inventories.

Previous studies have demonstrated the usefulness of word embedding for abbreviation disambiguation. Pooled neighbor word embedding of the abbreviations were used to train support vector machine classifiers for each abbreviation and the classifiers achieved good results on two clinical abbreviation datasets[5]. Use of deep contextualized word representation from pre-trained language model on large corpus has achieved state of the art performance on many NLP tasks, including abbreviation disambiguation[6][7].

In this study, we explored the use of deep contextualized word representations as the input features and the cluster analysis to divide instances into clusters for annotation. The annotated cluster would be used for subsequent classification.

2. Data and Methods

In this study we used the clinical abbreviation sense inventories from University of Minnesota (UMN)[8]. The inventory was derived from 352,267 clinical notes including admission notes, consultation notes and discharge summaries and included 74 abbreviations. For each abbreviation, 500 instances were randomly selected and annotated. For each instance, 10 words pre and post the abbreviations were extracted and used in this study.

The pre-trained BioELMo was used to get the contextualized representation of an abbreviation within each instance. Embedding from Language Models (ELMo) is a deep bidirectional long short-term memory (LSTM) language model with two hidden layers and achieves the state of the art results in several NLP problems (e.g. word sense disambiguation) due to its deep contextualized representation[6]. Embedding representation of each token in ELMo is a function of the entire input sentence. We used the BioELMo that was trained on the PubMed corpus with 10 million abstracts[9]. The first and second layers from BioELMo and summation of the two layers were used as the feature presentation in our study.

Instances from each abbreviation were divided into training (400) and test (100) data. Principal component analysis (PCA) was conducted on the word vectors of training data for dimension reduction. The PCA retained 95% of the total variance. The K-Means cluster algorithm was applied to extract 10, 15, and 20 clusters respectively. The senses of clusters were determined based on the majority vote of its cluster members. The trained PCA and cluster models were applied to test data to classify its sense. Simulation was conducted to evaluate the number of samples to be reviewed to determine the sense for a cluster. After the cluster analysis on the training data, we randomly sampled 1, 3 or 5 instances for each cluster per abbreviation to determine the sense of the cluster based on the majority vote. See Figure 1 for an overview of preprocessing and analysis process. The accuracy of classification was used to assess the performance of method.

3. Results

There were 74 abbreviations in the clinical sense inventory. Half of them had 3 senses and 8 abbreviations had more than 4 senses (Figure 2). Most of abbreviations had

unbalanced distribution of senses. 68 abbreviations had a sense accounting for over 50% of instances and 35 abbreviations had a dominant sense for more than 80% of instances.

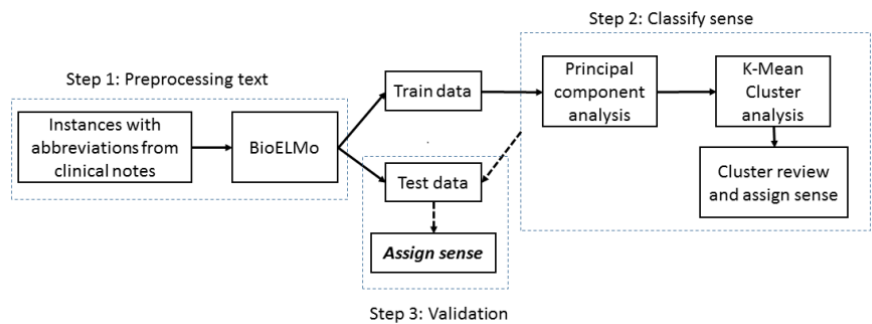

Figure 1. An overview of the method for clinical sense disambiguation.

Figure 2. Distribution of senses for the abbreviations.

Table 1. Accuracy of the method using different bioELMo layers and the number of clusters

Layer	Number of cluster	Accuracy on training data	Accuracy on test data
Layer 1	10	0.912 (0.072)	0.916 (0.087)
Layer 1	15	0.921 (0.065)	0.924 (0.076)
Layer 1	20	0.927 (0.064)	0.929 (0.076)
Layer 2	10	0.936 (0.060)	0.943 (0.065)
Layer 2	15	0.943 (0.057)	0.949 (0.062)
Layer 2	20	0.946 (0.051)	0.954 (0.059)
Sum of layer 1 and 2	10	0.930 (0.066)	0.935 (0.070)
Sum of layer 1 and 2	15	0.938 (0.056)	0.944 (0.058)
Sum of layer 1 and 2	20	0.943 (0.053)	0.948 (0.058)

Impact of ELMo layer and number of cluster on classification accuracy are presented in Table 1. Overall, use of layer 2 achieved better accuracy than use of layer 1 or sum of layer 1 and 2, and 20 clusters in the cluster analysis achieved the highest overall accuracy. Due to the nature of unsupervised learning used in our study, the differences in performance between training and test data were minimal.

Detailed results for each abbreviation are shown in Figure 3. For abbreviation with only 2 sense, there were minimal increases in accuracy when the number of clusters increased from 10 to 20. However, increasing the number of clusters improved the

classification accuracy in abbreviation with multiple senses. There were slight decrease of accuracy with the increase of senses, in particular for abbreviations with > 4 senses.

Simulation was conducted to evaluate how many instances were needed to be reviewed to determine the sense of a cluster. As expected, the increase of number of reviewed instances improved the classification accuracy. Use of 5 instances to determine the sense of a cluster achieved comparable overall accuracy to the use of all 400 instances.

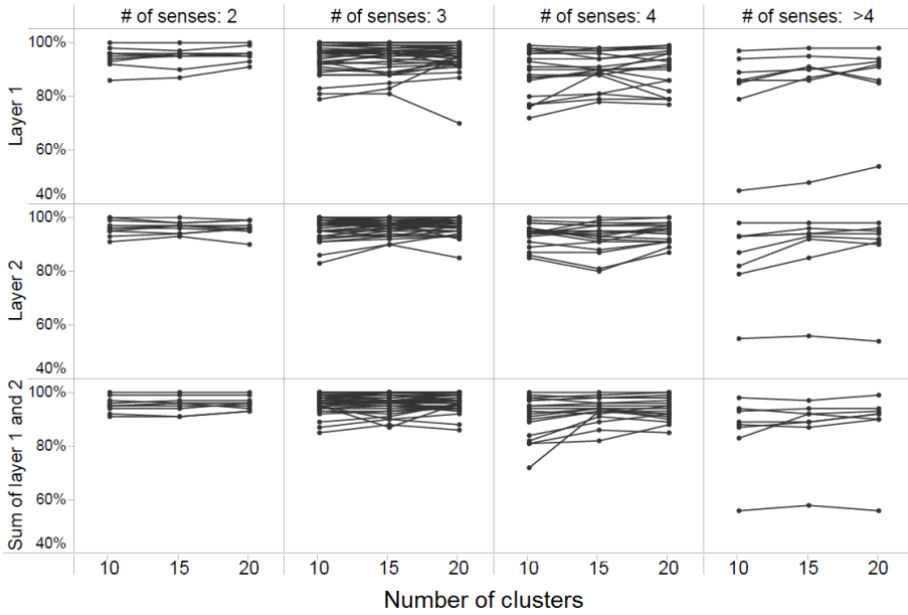

Figure 3. Impact of layer and number of cluster on the classification accuracy in test data. Each line represents one abbreviation.

4. Discussion

Our study showed that use of deep contextualized representations as features and cluster analysis to disambiguate clinical abbreviations achieved similar accuracy as supervised learning methods. Use of layer 2 of BioELMo and 20 clusters achieved the best performance. Simulation analysis demonstrated the potential cost-efficiency for sense disambiguation as it only required 5 samples per cluster without the loss of accuracy.

Use of word embeddings from pre-trained language models can capture rich semantic and contextual information for abbreviations and improve the accuracy of abbreviation disambiguation. The previous study used a bag of word representation, position information, and section name of clinical notes where the abbreviation occurs as the input features for cluster analysis and achieved an average accuracy of 93.7% on 12 abbreviations[4]. The use of deep contextualized representation as the input for a neural network model achieved an average accuracy of 98.1% on 11 clinical abbreviations[7]. This clearly shows the benefit of deep contextualized representation for abbreviation disambiguation.

Our method shows promising results on abbreviation disambiguation while requiring around 100 instances (20 clusters x 5 instances) for annotation to achieve comparable results to the supervised learning approaches. This could significantly reduce the cost of annotation. A recent study proposed the use of interactive learning algorithms to train abbreviation disambiguation classifiers using human created features[10]. During the annotation process, an expert was required to specify the sense of the indicated word and highlight the supporting evidence in a labeled instance. The algorithms achieved 90% accuracy using only 15 labels on the UMN dataset. Our method can achieve comparable results without the use of expert domain knowledge and steps to manually create the features for classification. This will speed up the development of new abbreviation disambiguation methods for new data sources.

Our study only applied the method in one corpus. Further investigation is required to test the generalizability of the method to other corpora.

5. Conclusion

We proposed the use of pre-trained language to extract deep contextualized representations for cluster analysis to disambiguate clinical abbreviations. The results show that with minimal annotation effort to determine the sense of each cluster, our method can achieve comparable accuracy as supervised learning methods.

Clinical Concept Normalization on Medical Records Using Word Embeddings and Heuristics

João Figueira SILVA ^a, Rui ANTUNES ^a, João Rafael ALMEIDA ^{a,b}, and Sérgio MATOS ^{a,1}

^a DETI/IEETA, University of Aveiro, Portugal

^b Department of Computation, University of A Coruña, Spain

Abstract. Electronic health records contain valuable information on patients' clinical history in the form of free text. Manually analyzing millions of these documents is unfeasible and automatic natural language processing methods are essential for efficiently exploiting these data. Within this, normalization of clinical entities, where the aim is to link entity mentions to reference vocabularies, is of utmost importance to successfully extract knowledge from clinical narratives. In this paper we present sieve-based models combined with heuristics and word embeddings and present results of our participation in the 2019 n2c2 (National NLP Clinical Challenges) shared-task on clinical concept normalization.

Keywords. natural language processing, clinical information extraction, clinical concept disambiguation, word embeddings, sieve-based model

1. Introduction

Electronic health records (EHRs) hold great value for the correct understanding of patient trajectories since they combine the multimodality in medical data with the temporal aspect that is embedded in the clinical history, rendering it as a vital component to correctly understand how symptoms, findings, diagnoses and diseases evolve [1].

Textual data is highly relevant and can be found in EHRs in (semi-)structured and unstructured formats, the latter being commonly referred to as free text. Medical narratives (e.g. discharge or admission reports) are stored as free text since natural language provides a flexible convoy for physicians to track and report each medical situation, overcoming the limitations from ambiguous and unspecific terms that physicians can find when using coding standards such as RxNorm or SNOMED-CT. Owing to that, it is reckoned that free text frequently contains plenty of information otherwise not obtainable from other data sources [2]. However, it is unfeasible to manually analyze large scale medical datasets. Despite the intricacies inherent to free text that make it very challenging to process and interpret, the process of automatically annotating clinical narratives is

¹Corresponding Author: Sérgio Matos, DETI/IEETA, Universidade de Aveiro, Campus Universitário do Santiago, Aveiro 3810-193, Portugal; E-mail: aleixomatos@ua.pt.

an important way to summarize or extract relevant data from medical text. This typically requires the text processing tasks of named entity recognition (NER) and named entity normalization (NEN) to extract relevant concepts and to standardize their referencing. The latter is a necessary step to combat ambiguities since clinical text contains many abbreviations, misspellings, and domain-specific expressions.

In this paper we describe an approach for normalization of clinical entity mentions using sieve-based models combined with heuristics and word embeddings. The proposed method was used in the 2019 n2c2 shared task on clinical concept normalization³, where the aim was to link clinical entities to SNOMED CT or RxNorm vocabularies through UMLS Concept Unique Identifiers (CUIs) [3].

2. Materials and Methods

The aim of the n2c2 clinical concept normalization task was to normalize medical entities to standard medical vocabularies. For simplicity purposes, the task focused only in NEN, bypassing the NER step by providing relevant clinical mentions identified *a priori*.

In this section, we describe the dataset used as well as the three different methodologies applied, namely a method based on concept embeddings, an improved version of a baseline sieve approach, and a final rule-based method.

2.1 Dataset

The Medical Concept Normalization (MCN) corpus proposed by Luo *et al.* [1] was used. It comprises a wider set of clinical concepts in contrast to previous NEN challenges that only evaluated the normalization of disease mentions [4,5].

Each annotated clinical entity is associated with a single CUI from the UMLS 2017AB version. For example, “hypertension” and “HTN”, or “blood pressure” and “BP” are two examples of expressions that refer to the same concepts and are therefore identified by the same CUIs (C0020538 and C0005824, respectively). Although UMLS encompasses several vocabularies, only two were used for annotation. RxNorm was used to annotate clinical drugs and medications, whereas SNOMED-CT, an extensive vocabulary of clinical terminology, was used for normalizing the remaining concepts (disorders, procedures, body structures, and others).

Table 1. Detailed dataset statistics.

	Training	Test	Total
Number of clinical records	50	50	100
Number of annotated entities	6 684	6 925	13 609
Number of unique CUIs	2 331	2 579	3 792

The dataset contains a total of 100 annotated discharge summaries and is split in training and test subsets (Table 1). This allowed model development in the training set and a blind official challenge evaluation using withheld test data (the gold standard annotations for the test data were only available after the official evaluation).

2.2 Developed Methodologies

2.2.1 Concept Embeddings Similarity

This method involves two sequential steps: (1) text pre-processing and (2) similarity computation. In the first step, certain text rewrite rules were handcrafted by inspecting the clinical named entities in the training set (Table 2) with the aim of cleansing the surface representation of these mentions. In addition to the text replacements made, HTML entities and other superfluous symbols were also discarded.

Table 2. Examples of text rewrite rules handcrafted according to the training set.

b/l	bilateral	po	oral	10%	partial
co2	carbon dioxide	trop	troponin	¼	fourth
e.	escherichia	u/s	ultrasound scan	x2	double
iv	intravenous	vit	vitamin	2L	two liters
mso4	morphine sulphate	w/u	workup	3 of 6	iii/vi

In the second step we represented the clinical named entities (from training and test sets) and UMLS concept names by using pre-calculated biomedical word embeddings. We employed the publicly available BioWordVec model [6] that was created applying the fastText library [7] and was generated from over 30 million documents from PubMed articles and clinical notes from the MIMIC-III database.

From these representations we created a direct mapping between terms and CUIs where each term was defined by the embedding vector average of its constituent words [8]. This mapping was built using (i) text mentions from the train set and (ii) concept names from the UMLS CUIs corresponding to the SNOMED-CT and RxNorm vocabularies.

At last, for making the predictions in the test set, the cosine similarity was calculated between each test mention embedding vector and all pre-calculated term embeddings [8]. The CUI corresponding to the most similar term was chosen.

A simplified overview of this method is shown in Figure 1. Due to its ability to correctly capture text mentions with similar semantics, this method was also used as a final sieve to predict remaining (unclassified) entities in the next two pipelines.

2.2.2 Improved Sieve-Based Approach

The sieve-based approach by Luo *et al.* [1] was firstly deployed, containing exact matching with the training set annotations and with UMLS, along with MetaMap sieves [9]. This pipeline was performed in two stages, firstly using raw text mentions and secondly using clean text mentions. This approach yielded a 5-fold accuracy on the training set of 0.783. An error analysis showed that MetaMap generated too many incorrect identifiers, limiting the number of unclassified mentions passing to the second sieve stage, thus capping the maximum attainable accuracy.

The pipeline was reworked by shifting the MetaMap sieve from stage 1 to the end of the pipeline, right before the MetaMap sieve from stage 2. Further improvements involved performing a Monte Carlo simulation to select an optimal threshold for CUI classification with MetaMap, greatly reducing false positives. Remaining unclassified mentions were classified using the concept embeddings approach described in Section 2.2.1. The final pipeline is presented in Figure 1.

2.2.3 An Orchestrator for Combining Simple and Complex Rules

This approach applies a 4-step pipeline combining rules and dictionary lookup, followed by previously computed concept embeddings.

The initial step processes mentions containing ambiguous terms that map to multiple CUIs in the training set. For each mention, several rules are applied that consider specific words from the respective sentence and section heading if applicable. In steps 2 and 3, the system performs an exact match using dictionaries created from the training set and the UMLS database, respectively. This three step pipeline is invoked twice: in a first phase it is applied to raw mentions, which was essential to detect certain patterns that could match concepts annotated in the training set; in a second phase, the remaining mentions are pre-processed as described in Section 2.2.1 before the pipeline is applied.

Finally, we combined this workflow with the concept embeddings from Section 2.2.1 by having a final stage where concepts that completed the previous workflow without an attributed CUI were processed using the concept embeddings.

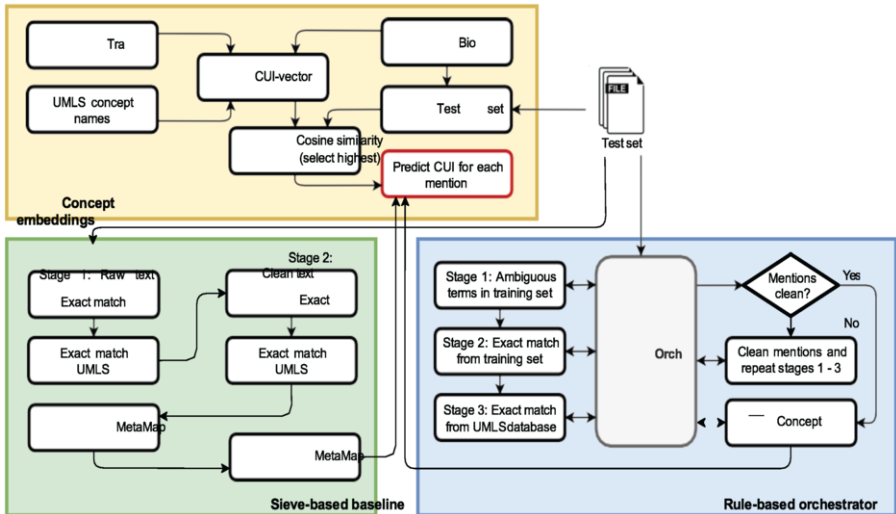

Figure 1. Final system architecture composed of three different approaches.

3. Results and Discussion

Table 3 shows the results, obtained in the training and test sets, of the three previously described methodologies.

Concept embeddings achieved an accuracy of 0.812 and 0.801 in the training and test sets. However, a posterior evaluation without using handcrafted replacements proved that the created text patterns were biased into the training set and led to overfitting, since simpler text pre-processing resulted in a lower training accuracy (0.807) and similar test accuracy (0.800).

The rule-based approach combined with the concept embeddings method obtained the highest accuracy in the test set with a value of 0.806, corresponding to a 4 percentage points improvement compared to the baseline sieve-based model proposed by Luo et al. [1] that obtained an accuracy of 0.764 in the test set.

Table 3. Obtained accuracy results with the three distinct methodologies. Results in the training set achieved by 5-fold cross-validation (10 repetitions in the concept embeddings method).

	Concept embeddings	Sieve-based	Rule-based
Training	0.812	0.806	—
Test	0.801	0.791	0.806

4. Conclusions and Future Work

In this paper, we proposed three methodologies to normalize clinical concepts from patient clinical reports automatically. The development of such methods applied in health-care data migration pipelines is essential to increase data value and have harmonized datasets.

As future work, we intend to improve each methodology individually by using information from the surrounding context and section heading of each mention. Also we intend to incorporate UMLS concept definitions to enrich the semantic knowledge regarding each concept. These improvements may reduce concept ambiguity issues. As a final refinement, we aim to apply deep neural network models to predict the correct CUI embedding vector.

Abstract. Chronic fatigue syndrome (CFS) is a long-term illness with a wide range of symptoms and condition trajectories. To improve the understanding of these, automated analysis of large amounts of patient data holds promise. Routinely documented assessments are useful for large-scale analysis, however relevant information is mainly in free text. As a first step to extract symptom and condition trajectories, natural language processing (NLP) methods are useful to identify important textual content and relevant information. In this paper, we propose an agnostic NLP method of extracting segments of patients' clinical histories in CFS assessments. Moreover, we present initial results on the advantage of using these segments to quantify and analyse the presence of certain clinically relevant concepts.

Keywords. Natural Language Processing, Chronic Fatigue Syndrome; Electronic Health Records; Clinical Informatics

1. Introduction

Chronic fatigue syndrome (CFS) is a debilitating illness characterised by extreme tiredness, with a wide range of related symptoms, including muscle fatigue and sleep disturbance [1]. Given that the origin of the condition is still unknown, analysing large amounts of patient data is an important step towards an improved understanding of its aetiology and clinical trajectories. Clinical assessments of CFS provide a comprehensive overview of patients' symptoms and functional limitations, and are usually conducted when a patient is referred to a specialist clinic. These assessments include past history as well as current situation, thus representing a valuable source of data for large-scale analysis. In electronic health records (EHRs), however, clinical assessments are often primarily documented in an unstructured form (free text), which cannot be easily analysed on a large scale. To allow the automatic analysis of such texts, natural language processing (NLP) methods are becoming increasingly popular [2].

During a CFS assessment, an extensive amount of patient information (e.g., demographic data, medication history, treatment plans) is gathered. To automatically

¹ Corresponding Author; E-mail: sumithra.velupillai@kcl.ac.uk.

process these different input texts, capturing only information specifically on factors that may have contributed to or are associated with symptom and condition trajectories is helpful. For downstream tasks such as clinical concept extraction and trajectory modelling, NLP methods that identify useful segments within the text are needed, and these are usually found in paragraphs related to *clinical history*. Automatically extracting these relevant segments for large patient cohorts is a challenging task, especially due to the variability of EHR document structures across healthcare institutions. In initial clinical assessments, most clinicians document the presenting (or primary) complaint first, and then less strictly ordered are the history of present illness, past medical and psychiatric history, family history, social history, personal history and assessment & management plan [3]. However, these sections are not necessarily documented under specific headings. There have been several efforts to develop NLP approaches that automatically extract document sections from various types of clinical documents, e.g., discharge summaries and admission reports [3–5]; family history [6–8], or patient histories [9]. However, most of these studies rely on using section and subsection *heading* information, which is often not available in a predefined way.

As a crucial initial step to modelling symptom and condition trajectory patterns in CFS patients, extracting clinical history segments from initial assessments - regardless of the structure of the documents - is needed. In this work, we develop an agnostic method of extracting temporal segments of text that convey clinical history information. The method is evaluated against a small set of manually annotated CFS assessments. We also perform an initial experiment of the potential benefit of using these segments to analyse the presence of certain clinically relevant concepts in a larger CFS patient cohort.

2. Materials and Methods

This study is based on mental health records from the Clinical Record Interactive Search database [10] from the South London and Maudsley NHS Foundation Trust (Ethical approval: Oxford REC C, reference 18/SC/0372). The first clinical assessment for CFS patients usually consists of a comprehensive letter written by the clinician, including information on past and recent history. To develop and evaluate our segment extraction approach, we used “first” assessment letters for all patients diagnosed with CFS - based on the date, length (character count) and title of the documents. 1201 patients (one document per patient) were identified. Only 49.7% of the documents had some form of section headings. 36 CFS assessments were randomly extracted and manually annotated by two annotators (medical students, native English speakers). Annotators were asked to mark *sentences* that indicated history information (clinical, family, personal and social history). Here, we only focus on sentences marked as *clinical history*. This annotated dataset was randomly split into a training (20 docs) and blind test (16 docs) set.

For our segment extraction algorithm, we hypothesised that historical segments contain more time expressions (e.g. *in 2012*, *two years ago*) than other parts of the document. Time expressions were obtained using SUTime [11]. The segment extraction algorithm divides each document in sentences using a regular expression sentence tokenizer. Then, it flags each sentence as 1 if the sentence contains a time expression (date or duration), 0 otherwise. The first and last sentence of each document are always considered as unflagged (0) because of document headings and end signatures. To generate larger segments, additional sentences are then flagged 1 if the length of the segment flagged as 0 between two sentences marked 1 is shorter than the average length

of segments with sentences flagged as 0. Finally, flagged segments that are too short are deleted, based on calculating the average length of flagged segments.

Inter-annotation agreement (IAA) was calculated with f-measure on the sentence level, which approaches the κ statistic when the number of negative cases is large and unknown [12]. For the algorithm performance, recall (sensitivity) was the main quantitative evaluation metric, calculated at a sentence level as compared to the annotators (A1 and A2). To assess whether the extracted segments retained clinically relevant information, we searched for a set of pre-defined concepts relevant to CFS disease trajectories within these segments and in the entire text (using exact string match). We considered the following concepts, known to be related to CFS: stress, virus, depression, anxiety and suicidal thoughts/ideation. The number of concepts were counted and compared in extracted segments vs. entire documents. In addition, two clinicians analysed the qualitative nature of the extracted segments for 10 randomly extracted CFS documents, assessing whether they retained the key clinical information. False positives and false negatives from the temporal segmentation algorithm were also analysed, to gain more insight into how temporal information is documented in CFS assessments.

3. Results

IAA on the CFS dataset was 70.6 and 74.9 f-measure on the training and test set, respectively. Overall, the temporal segmentation algorithm resulted in an average recall of 72.3% on the training set. Results on the final test set were: 64.1%.

Figure 1 is a visualisation of a random subset of the segments (training set) found by the temporal segmentation algorithm (black) compared to the manually annotated sentences (pink). Each document is divided into sentences. When a sentence

(x-axis) has been marked as clinical history either by the algorithm (black) or the annotator (pink), it is marked as 1, 0 otherwise (y-axis). As can be observed, the algorithm tended to cover most annotations (i.e. high recall), but also captured sentences not annotated as clinical history (i.e. low precision). In the qualitative evaluation, the clinicians generally agreed that the extracted segments usually contained symptom and condition onset information, and that they represented clinical histories.

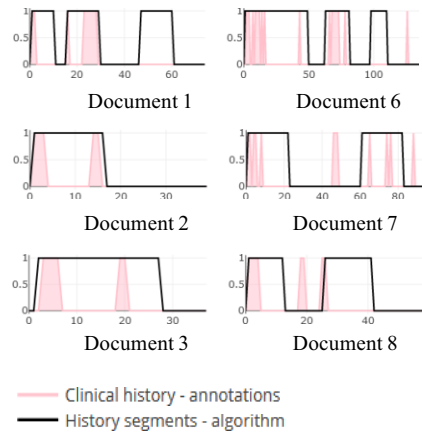

Figure 1: Visualisations of the temporal segmentation algorithm output as compared to manually annotated sentences (annotator A1) of clinical history on 6 documents from the CFS training set

Figure 2 shows results of the concept search on the entire set of CFS assessments (n=1,201). For 94% (1,133/1,201) of the patients (i.e. documents), at least one concept was found. ‘Stress’ was found in most assessments (69%, 832/1,201), and was, in the majority of cases, either in the extracted history segment (43%) or in both the history segment and outside (36%), i.e. in 21% the concept was documented only outside of the segment. ‘Virus’ was documented almost exclusively in the extracted history segments (11% were found outside of the segments). ‘Anxiety’ and ‘suicidal thoughts/ideation’ were more often reported outside of the history segments (30% and 34% respectively). ‘Suicidal thoughts/ideation’ was rarely found both within and outside the extracted segments (7%), and only found in 26% of the patients’ assessments (316). A manual analysis of 10 randomly extracted examples for ‘Anxiety’ and ‘Virus/viral’ (5 each) revealed some potential patterns. For ‘Anxiety’, all but one related either to speculations about the patient suffering from chronic anxiety disorder rather than chronic fatigue, or to anxiety related to work or health. For ‘Virus/viral’, 4/5 examples related to concepts that would be clinically relevant, and were all found at the beginning of the document, where the algorithm had failed to capture a segment. However, the segments in those documents contained synonym concepts such as ‘shingles’. The fifth example was a negation and was correctly excluded by the algorithm.

	Concepts found only in history segments	Some concepts found in history segments	No concepts found in history segments	Number of documents / patients
all concepts	26% [289]	64% [727]	10% [117]	1133
stress	43% [355]	36% [299]	21% [178]	832
anxiety	33% [181]	37% [199]	30% [163]	543
depression	48% [304]	28% [174]	24% [153]	631
virus / viral	73% [259]		16% [58]	356
suicidal thought(s) suicidal ideation	59% [185]	7% [24]	34% [107]	316

Figure 2: Coverage of pre-defined list of clinically relevant concepts in the entire set of CFS assessments

4. Discussion

To address the goal of finding population-level patterns in symptom and condition trajectories for CFS patients from their initial clinical assessments using NLP, selecting segments of the text describing the disease history is crucial. We have developed an algorithm that extracts temporal segments based on a simple approach relying on identifying time expressions (dates and durations) in sentences, and automatically expanding to segments by calculating patterns of consecutive sentences. As this method is agnostic to the data and does not make use of document section information, it can be extended to different types of clinical documents. In this approach, there is no assumption on the number of segments found per document. As shown in Figure 1, clinical history sentences can be either spread out across the document or gathered in one single segment. IAA agreement results were promising (within the ‘Substantial’ agreement range [13]), but further analysis and adjudication is needed. Most importantly, our current findings are based on a very small dataset – to generate more conclusive results, we will extend our study to larger datasets and perform additional experiments.

Previous studies on identifying segments in clinical narratives have heavily relied on the presence of pre-defined sections [3–5]. Only 50% of our data had section titles, thus such approaches would miss important information. We focused on improving recall, as our goal was to reduce the amount of irrelevant information in each document,

whilst ensuring we did not miss key clinical information. Generally, the algorithm covers the manual annotations (and more), but it also misses some sentences (Figure 1). False positives included examples of personal history rather than clinical history (#1 and #6) or current symptomology (#2). Several documents contained clinical history annotations at the end of the document (e.g. #6 and #7), that were missed by the current algorithm (false negatives). These corresponded to a brief overall summary which were repeating the information contained in previous segments. The algorithm also missed a few symptom-related sentences following a long social history paragraph (document #7). We plan to study alternative methods for automatically generating temporal segments based on larger datasets, as well as compare results with previously published approaches.

When searching for pre-defined clinically relevant CFS concepts, most documents had at least one (94%), and most concepts were found inside the extracted segments (90%). Concepts only found outside of segments were either mentioned in a different context than clinical history (e.g. the concept anxiety was used to describe the patient's current state) or used in the first sentence of the document (mainly for 'virus/viral'). We plan to extend this analysis by looking at additional concept mapping techniques such as word embeddings, clustering and topic modelling approaches.

Our main contributions in this study are: an agnostic method of extracting segments of EHR text that convey history information, and an initial experiment of the benefit of using these segments to analyse the presence of certain clinically relevant concepts in a CFS cohort. This is a first step towards large-scale studies on CFS disease trajectories.

Abstract. The ever-growing use of information and communication technologies in the past decades and the proliferation of mobile devices for monitoring vital signs and physical activity is enhancing the emergence of a new healthcare paradigm. More recently, citizens are becoming more sensible to the necessity of monitoring environmental health indicators and to its direct impact on personal health. This article proposes and describes the development of a clinico- environmental system for personal monitoring. The result is ContinuousCare, a personal healthcare information system that integrates personal smart devices with air quality monitors. The solution helps citizens to better understand their health and body activity with environmental context, aiding professional doctors with analysis tools and making available valuable data for external systems.

Keywords. clinico-environmental monitoring, health monitoring, personal health record, geolocation tracking

1. Introduction

The use of science and technology in medicine has been explored by mankind throughout the last decade more than ever. Information and communication technologies brought a proliferation of mobile devices for monitoring vital signs and physical activities of citizens and, consequently, the emergence of a new paradigm of medical monitoring is growing in the research communities.

On one hand, there already exists software to integrate distinct types of health monitoring devices and make available useful tools for injury detection and alert, amongst other purposes. Its target audiences are mostly specific groups like elderly people or athletes. On the other hand, the environmental conditions surrounding human life is often neglected by these healthcare technologies. Health disorders, painful conditions or even diseases can be directly correlated with local environmental conditions such as, for instance, high carbon dioxide levels. Current software solutions do not integrate environmental indicators, neglecting in consequence an important source of data than has tremendous potential to increase the prevention and diagnosis capabilities.

In this paper, we propose a personal monitoring solution called ContinuousCare that is able to integrate traditional personal health monitoring devices and environmental data sources, including home devices for air monitoring. Our system approaches the problem considering both the human activity and the environment it is exposed to and proposes powerful forms of data aggregation and visualization.

¹ Corresponding Author; E-mail: filipesnetopires@ua.pt

2. Background

A market research and literature reviewing process was performed for evaluation of actual proposal in the scope of ContinuousCare solution. It is possible to find a tremendous number of products, services and reports related to personal health monitoring, including geolocation recording. Due to the article size restrictions, we just report the ones that were more inspiring to the proposed system. An android application [1], developed by Turkish researchers, was the first product that takes advantage of geolocation to improve its service's quality. The application allowed users to keep track of elderly family members and be notified in case of emergencies, providing the closest hospitals. Health Tracking system [2] used GPS coordinates and other metrics to provide insights on the physical conditions of cyclists. The offered services seems very interesting and were inspiring for our proposal, being adapted to a more generalized target audience. Other solutions such as the Angel-Echo [3] or the UPHSM [4] provided us with perspectives on the potential of the subject and on the variety of use-cases and target audiences that could benefit from robust and intuitive health monitoring systems. Finally, the evaluation of key characteristics of already existing products, for similar problems, were taken in consideration during the design of ContinuousCare. A group of students from SSPACE college [5], in India, gave us valuable insights on what are the best metrics to take in consideration when monitoring body status.

3. System Architecture

The architecture of proposed personal monitoring system is shown in the Figure 1. The key design decisions aimed to ensure the robustness and scalability of ContinuousCare and its accessibility to any user with an internet connection. These regarded the collecting of data from our different sources, the appropriate storage strategy and the database load and access-time optimizations. It follows a modular structure where each module is replaceable and updates to one component do not imply the refactoring of others. The main component is the Monitoring Server that is divided into 3 functional units:

- Processing – it is responsible for gathering the information from supported devices and public data source APIs. This operation is scheduled, which means that it is executed many times per day. This unit is responsible for doing this scheduling and for processing the data collected (filtering it, assigning labels, and more);
- Persistence – it is responsible for storing all data after processing. It interacts with the database interface and ensures that every field is persisted correctly;
- REST API – it is the component responsible for supporting a REST (REpresentational State Transfer) interface for the system, serving as the entry point for every client application.

The second module is the GPS Service that was implemented since many personal monitoring devices do not provide access to its locations. Since geolocation is a crucial aspect in our proposal, it was necessary to implement from scratch a service responsible for receiving the users' locations and a mobile application that tracks them.

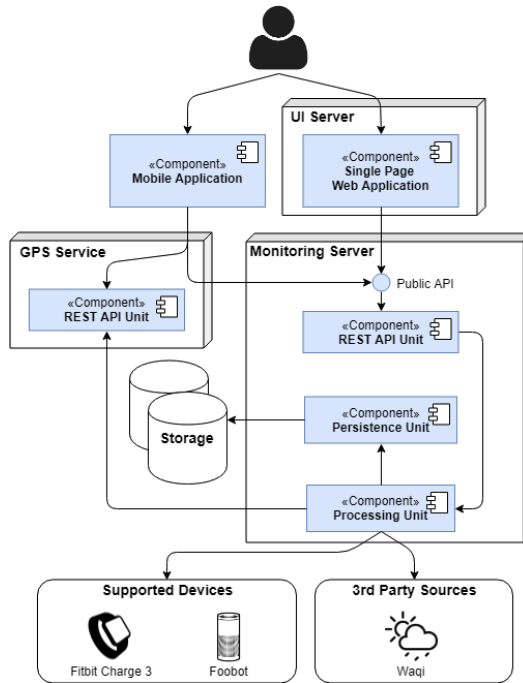

Figure 1. Architecture diagram.

In the persistence layer, we adopted a strategy based on a hybrid database. It was designed a relational database model in MySQL for the structured and interconnected data: accounts information, permissions between users, and devices. For the bulk data received from the devices and external sources, it was used a time series driven database, implemented with InfluxDB. This second one was found the best technology for our case as it is dedicated to continuous data streams and queries with time intervals. It is this database that feeds most of our web application's features. A system like ContinuousCare faced problems of big-data and some optimizations were performed, namely keeping in cache the values for a given time interval and periodically writing all the values stored with a batch process. In the long run, the database will hold a big load of data, some of it turning irrelevant as time passes. For this reason, the storage module supports the aggregation data after a defined period of time.

The platform provides a web application that runs on the UI Server and is our main interface with the end-users. It interacts with a public REST API (through the Monitoring Server) and makes use of the supported devices. It was developed with the NuxtJS framework, over VueJS, helping to maintain an intuitive website organization and giving us the possibility of deploying either a Single Page App or a Universal App (where pages are rendered on the server side for a smoother user experience). Several libraries for graphical elements, cookies and web-sockets were used, as well as an HTML template from Colorlib [6] for design purposes.

Finally, the system supports at this moment three types of data providers: 1) personal monitoring device – it was used the Fitbit Charge 3 [7], an advanced fitness tracker that has many health-related metrics. We focused on collecting calories, heart rate and sleep stages, as these present more interesting information for analysis

purposes; 2) air quality monitor – it was used Foobot [8], an indoor device able to detects invisible and odorless pollutants that fall into 3 categories (volatile compounds, particulate matter and carbon dioxide), calculates temperature and humidity levels and alerts users about unhealthy activities; 3) public portal with environment indicators – it was used the Wapi² public API that allows us to know the level of pollution of a given place on earth. By tracking the geolocation of our users, the system is able to decide whether to collect information from a Foobot or from Wapi according to the distance between the users and their respective air quality monitors.

4. Results

A Web platform was deployed on the Cloud with all functionalities described in this article. The system was continuously used by a user during one month for validation purposes. The platform supports two distinct user profiles, patients and doctors. Doctor accounts, once permitted by patients, have access to the profile information and to all records, grouped by Health Status, Environment, Sleep or Events. In each group, the user can see a particular metric in detail throughout time with the help of the line graphic. Users are able to add, remove or update monitoring devices. For instance, they can have many home devices in different places of common use (home, workplace, etc.).

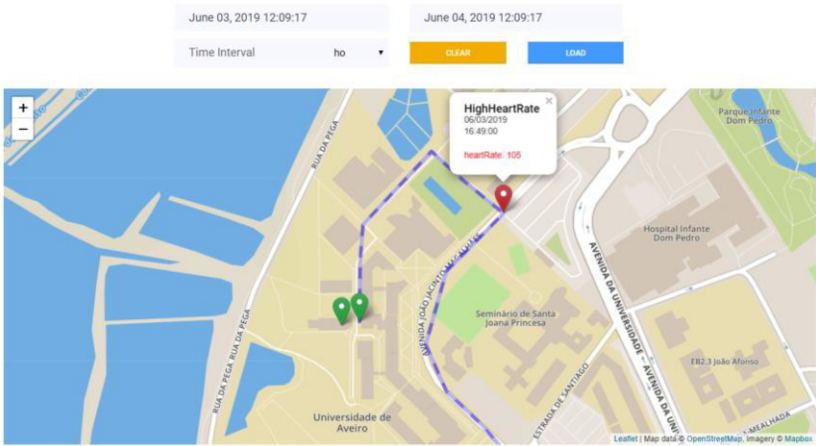

Figure 2. History Page

Users have also available a timeline with relevant events that occur throughout the days. The users can add descriptive markers (annotation) to those events to keep track of their health progress. They include situations like, for instance, heart rate out of the healthy range, presence of high levels of carbon dioxide or other harmful particles, sedentary behaviors (not enough daily steps), few hours of sleep, etc.

Figure 2 presents one of the most emblematic functionalities implemented, the History Page. Here the user can see the places he/she has been, the current location of his/her device(s) and the markers of events that occurred throughout the defined time window. This allows the pairing of events to locations and understand what places

² <https://waqi.info/>

affect him/her the most.

The first version of ContinuousCare application provides 7 main functional areas and presents data related to 20 metrics. Its public API provides 26 public endpoints (i.e. services). The results of the scalability tests executed show that the backend supports comfortably 100 users online, each making 300 requests, ensuring all of the performance requirements established.

5. Conclusions

Modern society is becoming very sensible to the necessity of monitoring environmental conditions and study its impact on personal health. This paper proposes an innovator clinico-environmental system for personal monitoring. ContinuousCare presents itself as a healthcare tool for any person, empowering both people concerned with their own health and medical personnel looking for innovative analysis tools. It has potential to aid any user interested in perfecting their lifestyle and monitoring the surroundings. It combines data collected by air quality monitors with vital signals from personal health devices, and it makes all data collected easy to read, process and consume in an integrated way. Users can also annotate detected events and register daily moods and behaviors. In the future, the efforts will focus on a new system module for data mining aiming to extract key information from events and offer tools to predict diseases and notify users of dangerous behaviors and hazardous environments.

Abstract. Grenoble Alpes University Hospital (CHUGA) is currently deploying a health data warehouse called PREDIMED [1], a platform designed to integrate and analyze for research, education and institutional management the data of patients treated at CHUGA. PREDIMED contains healthcare data, administrative data and, potentially, data from external databases. PREDIMED is hosted by the CHUGA Information Systems Department and benefits from its strict security rules. CHUGA's institutional project PREDIMED aims to collaborate with similar projects in France and worldwide. In this paper, we present how the data model defined to implement PREDIMED at CHUGA is useful for medical experts to interactively build a cohort of patients and to visualize this cohort.

Keywords. Complex and massive data, medical informatics, health data warehouse, cohorts, data visualization

1. Introduction

Selecting a cohort of patients and gathering associated medical data for research usually involves bringing together information from different sources, potentially isolated from each other in a hospital's information system.

It is thus necessary, for all patients that are likely to be members of a research cohort, to combine their clinical notes with the local information of a clinical department of the hospital, then to enrich them with those distributed in the various hospital databases, to gather all the documents containing demographic, clinical, biological, pharmacological information concerning these patients. This phase often

involves the cooperation with the IT department to transform the potentially complex needs expressed by the research team into querying language to extract the expected information from the hospital's multiple databases. Several iterations of this process between researchers and data managers may be necessary to ultimately lead to the expected data set. However, in this way no interactivity on data exploration is offered to researchers, though it would allow them to obtain or approach faster the best possible result. It is then necessary to organize these data in a coherent and easily explorable form for researchers to select the members of the final cohort that will constitute the data set to be used for the study.

The whole process of collecting the data set associated with a cohort of patients is therefore expensive in terms of mobilizing different health and IT specialists for several months. This paper describes methods and tools implemented as a proof of concept in the framework of the health data warehouse called “PREDIMED” of the Grenoble Alps University Hospital, to enable hospital authorized medical specialists to navigate interactively and in a fluid way through the whole data lake or through their own data set, to create and explore their own cohorts of patients.

PREDIMED is a data lake platform designed to integrate and analyze for research, education and institutional management, the data of patients treated at CHUGA since 1998. PREDIMED contains administrative data (patients and visits), healthcare data (diagnoses, prescription, images, etc.) and, potentially, data from external databases. PREDIMED is hosted by the CHUGA Information Systems Department and benefits from its strict security rules. PREDIMED has several views on the data facilitating its exploration and usage according to the specific needs. In this paper, we specifically present the graph model and the associated tools dedicated to its real-time exploration and data visualization of millions of heterogeneous information.

2. Methods and implementation

Here we describe methods and implementation choices that we used to provide healthcare professionals with an environment allowing them to simply and graphically manipulate the concepts and relationships of their expertise domain to navigate through the hospital's data lake without knowledge of any computer language.

Figure 1: Graph data model of the data lake and interactive cohort construction interface.

The data lake is modeled in an intuitive form that allows each member of the research project, regardless of their profession, to understand its semantics [3]. Figure 1 gives an idea of the graphical visualization of the lake data model. Graph nodes are common medical concepts and graph edges represent the relationships between them.

Patients data from various hospital databases is linked in PREDIMED via an internal key. This technical key is different from the patient number used for care to separate medical information from directly identifying data. The same approach is used for the visit numbers.

Using the graph data model, the team in charge of cohort constitution works with the clinician to build the cohort for the study. The graph model allows starting from any entity since the selection is made by choosing a concept from the model and following an edge that links it to another concept. The traversal can thus start from diagnostic codes (ICD10), periods of hospitalization, administered treatments or any other graph node. The user can then progress in traversing the graph edges by hops, possibly expressing constraints at different levels. Interactively, at each movement through the graph, the system provides the volume of collected data. In Figure 1, one can see that at this intermediate stage, the selected data concerns the entities marked in yellow (here *diagnostics*, *patient_id*, *document*, *venue_id* and *treatment*). The attributes associated with *venue_id* can be filtered (a filter can be set on the hospitalization period (*dt_debut_prestation* for example)).

Behind this graphical selection mechanism is a query language [4] specifically developed for the project that allows the user to query the associated graph database. The query basic hop is built as follows:

“source objects class”[filters]—named relationship[filters]—> “target objects class”, ...

The complete query string that traces the graphical navigation path is associated with the current cohort, which allows the user to relaunch it if the lake content gets richer or to trace what has been done during the exploration phase.

Figure 2 illustrates the expression language of a textual query for the first move through the graph. The presented query is based on a proof-of-concept study building a cohort of patients with diabetes (first move in Figure 2: patients over 20 years old, hospitalized in 2016 and whose biological measurements and received treatments corresponded to the chosen characteristics).

Figure 2: Generated query hop during navigation

3. Results

Through the interactive iterations on this graph, the clinician can visualize the information on the obtained cohort in different ways. Graphical visualization tools associated with the cohort make it possible to highlight the dispersion of patients over the territory or to construct a dashboard with various indicators (see Figure 3).

Based on the same data structure, a visual exploration of the cohort being built provides access to a “360° view” of the cohort elements. The visualization interface in a web browser interacts with the graph database through a software layer (REST API)

that gives an abstraction of the model. This architecture thus limits a strong adherence with the database.

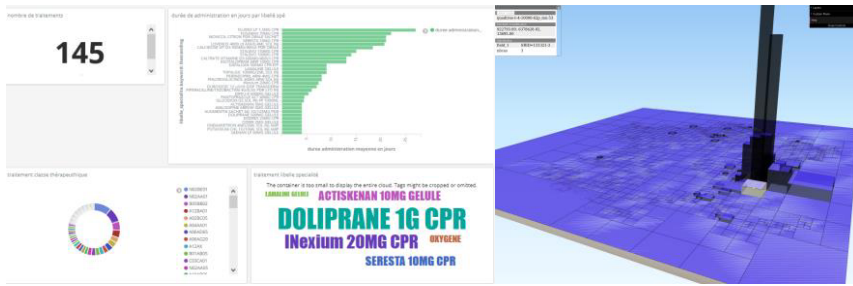

Figure 3: Interactive views describing the current selected data-set

This “360° view” of the patient allows to visualize the different sides of the patient file. The first facet resumes the diagnoses based on the ICD10 codes and the timeline provides the chronology of these diagnoses. Those codes are projected onto a body silhouette highlighting the affected organs or body parts. An oval-shaped representation gives a synthesis of the pathological classes concerned. Other facets provide access to the various documents available in the patient's file. As with diagnoses, a timeline is associated with the list of documents such as drug prescriptions. An equivalent view is available for pharmaceutical prescriptions giving both the list of drugs administered or prescribed (therapeutic class, name of the drug, etc.).

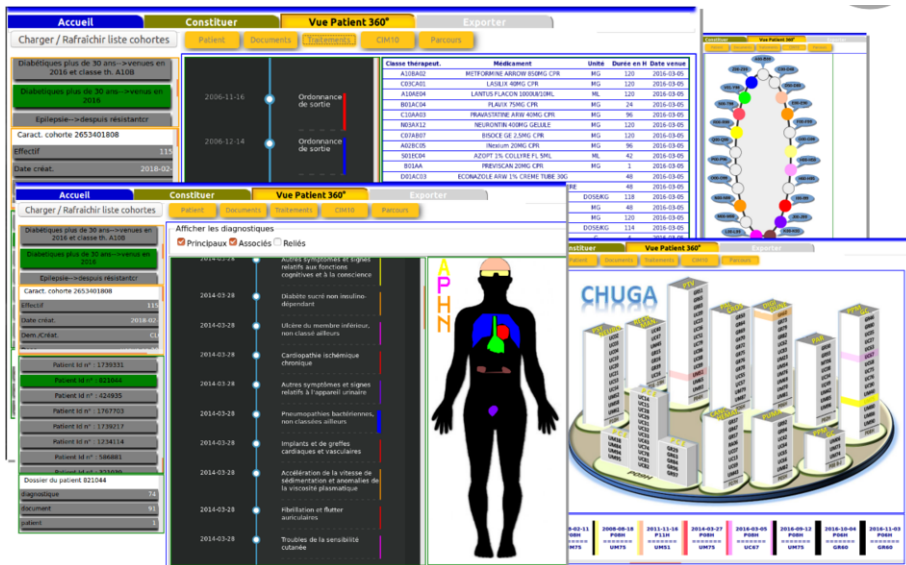

Figure 4: Different views on the patient's file.

4. Discussion

4.1. Flexibility, evolutivity of the model, code genericity.

Graph modeling allows similar concepts to be grouped together and is well-suited to represent flexible and evolving structures. Graph data model implementation with a

graph database is almost straightforward and the high level of manipulated objects is appropriate for the development of generic code, independent of the future data variants.

4.2. Implementation and interoperability

The application environment we have built to operate PREDIMED is based on an open source property graph database, ArangoDB. This in-memory system enables to navigate seamlessly in such complex, highly-connected, massive data organizations. The native JSON-centered data application environment provides both the ability to comply with normative health data standards, to deal with complex objects' attributes (lists, matrices...) and the ability to distribute processing on different and evolutive applications of the PREDIMED architecture. Interoperability is also facilitated by the ability to interconnect with other graphs, using online APIs provided by evolving global data standards for health information such as ICD11.

4.3. Scalability

Unlike a conventional relational database system whose complete request must be written in advance, PREDIMED's alternative request system allows researchers to navigate easily through the data and record the path corresponding to a “built-on-the-fly” request. As the request is executed step by step, even when it is eventually relaunched entirely, there is potentially no limit to the number of steps that constitute the response path to a request. The size of the request and therefore its complexity have no impact on the processing infrastructure.

5. Conclusion

PREDIMED Data Warehouse allows non-IT specialists to use complex and massive data mining tools to effectively and rapidly design patient cohorts for research projects. PREDIMED provides agility and auto-improvement ability in data navigation while making the work traceable, reproducible, and transferable to other data-sets.

This work has been performed as proof-of-concept. The independent supervisory authority in terms of the GDPR (CNIL in France) has authorized the CHUGA to proceed to the operational phase of PREDIMED, on October 10 2019.

Abstract. The use of Artificial Intelligence (AI) technologies within the healthcare sector is growing. However, there are differences in the speed of commercial adoption of AI across sub-sectors. We employ a dataset including news mentions and executive communications of all S&P500 Health Care Index companies to explore these differences. Pharmaceutical and medicine manufacturing companies had the earliest AI-linked news presence, yet they appeared to be among the slowest commercial implementers of AI. Ambulatory health care services and hospitals, as well as insurance carriers, received media coverage later, but were the quickest to take AI into commercial use. From the theory perspective our results indicate that the classical innovation diffusion theory might not fully explain these differences.

Keywords. Artificial Intelligence, Technology Transfer, Health Technology

1. Introduction

Artificial intelligence (AI) technologies are expected to significantly impact or even transform healthcare provision. Value of goods and services produced by 12 developed economies in the healthcare sector alone is estimated to exceed baseline growth by USD 400 billion in 2035 thanks to the use of AI [1]. However, such value creation and capture can take place only when the technology is translated into action [2]. To understand this transition, information technology (IT) diffusion and assimilation has been one of the central areas of investigation in healthcare informatics [3], information systems [4], and innovation literature [5]. Due to the increasing applications of AI in healthcare, there is a need for studies exploring the status of commercial adoption of AI within that sector.

This paper reports results from an exploratory analysis focusing on the adoption and commercial use of AI technologies by large healthcare companies. We investigate AI and machine learning (ML) related keyword appearances in two contexts for the sample of 62 healthcare sector companies, which were constituents of S&P500 index as of May 2019. The first context is news and media items that relate to the sample companies and include AI or ML keywords. The second context is earnings calls and other investor presentations of the sample companies, where top executives make statements regarding commercial applications of AI and ML technologies.

2. Data and Methods

Sample of companies selected for this study consisted of S&P500 Health Care Index constituents included in the index as of May 2019. These companies represent some of the largest healthcare companies in the world and are thoroughly covered by news and media, as well as financial analysts. Consequently, there is a large body of publicly available information regarding these companies, which makes a research design leveraging content analysis a feasible approach. The sample companies were divided into six sub-sectors based on their NAICS codes (manufacturing companies were further divided into two subgroups). Following [6], we do not intend to provide explicit definition of AI, but rather rely on implicit definitions embedded in the examples covered in the analyzed content. Nevertheless, our work was guided by an inclusive definition as follows, “Artificial Intelligence . . . is intended to make computers do things, that when done by people, are described as having indicated intelligence” [7].

For each company, we collected data from two sources. News and media items were collected from ProQuest ABI/INFORM Collection using the following search query: *("artificial intelligence" OR "machine learning") AND stype.exact("Magazines" OR "Trade Journals" OR "Newspapers" OR "Reports" OR "Blogs, Podcasts, & Websites" OR "Wire Feeds") AND la.exact("English")*. Transcripts of management presentations were retrieved from Thomson Reuters Eikon database. The types of items searched included not only transcripts of quarterly earnings calls, but also other conferences, media events, financial analyst days and investor events. The case insensitive search query used for that database was: *"artificial intelligence" OR "machine learning"*. The time period covered in this exploratory analysis was 1 January 2004 – 10 May 2019.

Preliminary qualitative analysis focused on the transcripts of management presentations. For each company, the transcripts were analyzed by two researchers to determine whether a commercial application of AI technologies has been mentioned. The definition of commercial application was either (1) reference to a current commercial use of AI or ML technologies (as part of customer offering or internal processes, which are “business as usual”), or (2) commercial launch or implementation utilizing AI or ML technologies in the near future (specific details provided).

The subsequent exploratory analysis had two objectives: (1) to establish the current status of AI use by healthcare sector companies and (2) to inspect the pattern of diffusion of the technology over time with the intention of identifying aspects requiring scrutiny.

3. Results

Nearly all companies (91.9%) included in the sample have been mentioned in news and media in the context of AI, and 43.5% of companies have mentioned commercial use of AI technologies during their investor presentations given by top executives (Table 1).

It appears that news and media coverage in relation to AI and healthcare companies increased sharply starting from 2015. Major increase in number of companies mentioning commercial use of AI during their investor presentations started in 2017. Figure 1 provides more detail on the cumulative percentage of companies covered in news and media items related to AI, as well as those mentioning commercial use of AI.

First mentions of AI in news and media items covering healthcare companies, in many cases, have been far ahead of the recent wave of AI technology implementation by the companies. This is particularly the case for manufacturing companies (sub-sectors 1

and 2). Figure 2 illustrates the publication timings of news and media items. 98% of the items were published during the last four years.

Table 1. Summary statistics for news and media items mentioning sample companies and AI technologies, and top executive investor presentations mentioning AI technologies.

Sub-sector	News and media items			Top executive presentations		
	Count	Mean count per company	Mean date of 1st mention of AI/ML	Count	Mean date of 1st commercial use mention	Share (ratio) of companies with commercial use
1. Manufacturing (excl. Pharmaceutical and Medicine)	721	28.8	2014-11-11	81	2018-08-17	48.0% (12/25)
2. Pharmaceutical and Medicine	1 661	127.8	2013-04-02	14	2019-11-12	15.4% (2/13)
3. Professional, Scientific, and Technical Services	254	31.8	2016-05-04	28	2018-11-27	37.5% (3/8)
4. Ambulatory Health Care Services and Hospitals	327	36.3	2016-12-19	18	2017-10-21	66.7% (6/9)
5. Merchant Wholesalers	148	37.0	2017-09-02	4	2019-11-17	25.0% (1/4)
6. Insurance Carriers	214	71.3	2015-07-16	23	2013-07-09	100.0% (3/3)
Total	3 325	53.6	2015-03-27	168	2018-08-21	43.5% (27/62)

Figure 1. Comparison of cumulative percentage of companies mentioned in AI related news and media items with cumulative percentage of companies mentioning commercial use of AI in executive presentations.

A sub-sector level comparison of cumulative percentage of companies mentioned in news and media in relation to AI, and those whose top executives mention commercial use of AI reveals stark differences. Manufacturing (1 and 2) and Professional, scientific and technical services (3) companies started appearing in news and media items in a relatively even manner over time. The remaining sub-sectors started receiving news and media coverage much later, yet they caught up or even exceeded early-comers. See Figure 3 (left). This pattern is nearly reversed when mentions of commercial uses of AI are considered. See Figure 3 (right). Insurance carriers (6) and Ambulatory health care services and hospitals (4), which received news and media attention later, were not only the first ones to mention commercial uses of AI, but these sub-sectors present also the highest rate of disclosure regarding commercial use of AI. Contrary to the news and

media coverage, Pharmaceutical and medicine manufacturing (2) companies appear to have the lowest rate of commercial utilization of AI.

Figure 2. Timing of AI related news and media mentions of healthcare companies. Each row in the chart represents a single company.

Figure 3. Left: Cumulative percentage of companies mentioned in AI related news by sub-sector. Right: Cumulative percentage of companies with commercial AI mentions in executive presentations by sub-sector.

4. Discussion and Conclusions

Companies from pharmaceutical and medicine manufacturing subsector had the longest and most prominent news and media presence, yet they were among the slowest commercial implementers of AI. Ambulatory health care services and hospitals, as well as insurance carriers received news and media coverage much later, although more rapidly, and were the quickest to take AI technologies into commercial use. Larger media coverage might be a result of pharmaceutical companies having typically a long product developmental timescale, resulting in relatively larger overall fixed costs and possibly also driving larger marketing budgets, thus leading to increased press coverage. AI solutions developed for pharmaceutical companies are also found to attract more venture capital funding than other healthcare-related AI solutions [8].

Classical diffusion of innovations theory (DOI) [5] predicts that new technologies, such as AI, do not spread evenly across the whole population. Instead, a typical cumulative adoption curve takes an “S-shape”— the sample companies taken as a single group appears to follow such pattern (Figure 1). However, sub-sector level analysis and

comparison of news and media coverage (approximating diffusion of information and awareness) with mentions of commercial uses of AI by top executives (approximating diffusion of commercial adoption) indicate that DOI might not fully explain the sub-sector level differences. Disparity between these two diffusion patterns indicates that factors beyond those recognized by DOI might be at play, which is a phenomenon requiring further investigation. From media perspective, the solutions for e.g. insurance carriers might be seen as having less public impact potential than pharmaceutical products [9]. Furthermore, organizational characteristics such as IT intensity and absorptive capacity or use case of AI, such as those illustrated by quotes in Table 2, might explain AI adoption rates [4]. In our future research we intend to further investigate factors driving AI adoption by healthcare companies.

Table 2. Quotes illustrating organizational characteristics and use cases, which might impact AI adoption.

Sub-sector	Quote
1. Manufacturing (excl. Pharmaceutical and Medicine)	“Tempus combines Illumina’s sequencing with machine learning to provide physicians a comprehensive report that highlights key findings to support clinical decision-making.”
2. Pharmaceutical and Medicine	“[...] many different kinds of data sciences we had to bring together. So add to this list graph theory, non-linear machine learning, lot of combinatorial methods, and I’m even going to show you how we’ve used elements of cryptography in some of the analysis...”
3. Professional, Scientific, and Technical Services	“[W]e will leverage [...] machine learning, human genetics and functional genomics to create disease models for NASH and discover relevant drug targets...”
4. Ambulatory Health Care Services and Hospitals	“We use real-time machine learning. We know the demand patterns that are coming into our patient service centers, so we can make real-time staffing decisions and we can take some of the staffing decisions out of the hands of the supervisors and tell them exactly what they’re going to need at that facility next Tuesday at 9:00 in the morning.”
5. Merchant Wholesalers	“[W]e’re basically using machine learning, artificial intelligence to do online claims adjudication, which will make us so much more efficient and so much more scalable...”
6. Insurance Carriers	“[W]e process about 2 billion claims a year, about \$0.5 trillion in medical spend and we transmit about \$130 billion in funds electronically every year and we do so to about 1 million care providers across the country. [...] all of that represents data and [...] increasingly, we’re applying machine learning...”

A Computational Adverse Event Detection Matrix

Mary GADDE ^a and Melody PENNING ^b

^a University of Arkansas, Little Rock, Arkansas, United States ^b Department of Biomedical Informatics, University of Arkansas for Medical Sciences, Little Rock, Arkansas, United States

Abstract. Harms caused during healthcare encounters are pervasive and occur at an alarming rate; therefore, building a set of computational detection methodologies in the adverse event area is urgently needed to address this problem. To understand the entire range of adverse event detection methods currently in practice we have developed a computational adverse event detection matrix. This structure is made of methods used presently at US hospitals to detect patient safety events. It contains adverse event 1) concepts and 2) synthesized detection strategies as well as calculations of overlap of coded data in the subset of algorithms implemented completely computationally. Most importantly, this matrix provides a clear picture of coverage gaps in the detection of adverse events.

Keywords. Patient safety, Data quality

1. Introduction

Harms or Adverse events (AE)s caused during healthcare encounters are pervasive, have a significant impact on patient wellbeing, and occur at a staggering rate. Specifically, one of every ten hospitalized patients develops a healthcare-acquired condition, and twelve million outpatients experience a diagnostic error, which may result in harm, every year. [3] AEs can be categorized as unavoidable (e.g. part of the patient's condition), potential (near miss or never events) or preventable and can come from active medical errors at the point of care or latent causes present within care settings. [9; 13] The Institute for Healthcare Improvement uses a definition for AEs as "Unintended physical injury resulting from or contributed to by medical care (including the absence of indicated medical treatment), that requires additional monitoring, treatment, or hospitalization, or that results in death".

This study is designed to determine which of the events designated as harms, or AEs, are currently 1) identifiable algorithmically, 2) which are identifiable using other methods, and 3) which are likely going undetected due to the methodology used. AEs are typically tracked and quantified using incident reporting, medical record review or claims data, although other methods are also available, as shown in Table 1. None of these processes captures all AEs.[10] Comparative studies suggest that the most effective methodology is the Medical record review (MRR).[9] As this process is time-consuming, efforts have been made to increase the efficiency of this work with instruments like the Institute for Healthcare Improvement (IHI) Global Trigger Tool. [3; 7]. To ensure as many AEs are detected as possible while at the same time not overloading healthcare staff automation has been introduced in several of the methodologies listed in Table 1. Detecting AEs using rule-based algorithms makes automation possible. [8] But this

automation is only as good as the combination of the phenotype definition and the data it consumes. Not all AE will be detectable using rule-based algorithms. Active errors occur at the point of contact between the patient and the healthcare system and are typically observable whereas latent errors are process errors, where no single event is the source of the problem. AEs arising from active errors are more detectable than those arising from latent causes, and direct process observation or data mining are the best solutions to finding these types of situations. In general, the methods listed in Table 1 can miss as much as 90% of all AE types. [5]

Table 1. AE Detection Methods Currently in Use

Medical Record Review (w/ and w/out Trigger Tools)
Studies based on interviews w/ healthcare providers
Direct Observation
Incident Reporting Systems
External Audit
Studies of legal claims and complaints
Administrative Data
Computational Methods using EHR
Autopsy

We are currently in need of common terminology to quantify the occurrence of and detection methods for AEs. In the US, governmental organizations and Patient safety organizations (PSO), regulated by the US Agency for Healthcare Research and Quality (AHRQ), collect data and do analysis and reporting on patient safety concerns. Many of these organizations have designed approaches to describe, classify and detect patient safety events. Methods used include retrospective surveillance with administrative coded data, observation and voluntary reporting as well as MRR. All of these methods are flawed in that they miss AEs or are excessively expensive so cannot be conducted at scale. [12; 14] Additionally, large scale detection methods are not sensitive enough to show improvement over time. [3]

In an effort to find common ground among the methods currently in practice, we have developed a computational AE detection matrix. This matrix provides a clear picture of what is available and what is missing in the detection of AEs. As part of this process we have also investigated the overlap in computationally implemented algorithms.

2. Methods

In order to understand where there is overlap in current AE detection methodologies and to discover which AE are not the subject of *in practice* methodologies, we have classified currently accepted PSO AE detection algorithms into the International Classification for Patient Safety categories from the World Health Organization (WHO). Patient safety information is categorized into standardized concepts that represent descriptions that are valid internationally and can be used for comparison, measurement, monitoring, analysis and interpretation of information for improved patient safety.[15] This framework breaks patient safety events into ten high-level classes which are broken down into very specific but generalizable concepts two of which are directly comparable to the PSO terminology, incident type and patient outcomes. Although, some incidents may be classified in more

than one category in the WHO framework we have kept to a one to one relationship with detection algorithm.

Right now, there are a few standard approaches to AE detection and none are both highly efficacious and also computational. Some are completely computational and can detect roughly half of AE [1], and some use MRR, which is very thorough but limits the number of cases evaluated due the time required. In previous studies commonalities among detection strategies were synthesized and found to be predominantly focused in the areas of surgery and care management.[11] This study seeks to extend the previous work by including areas in healthcare where AE are recognized, but no external detection method is currently in place to identify them. This work includes the extraction of the rule-based definitions. For the computational approaches, the extraction of International Statistical Classification of Diseases, Injuries and Causes of Death (ICD) codes used in the detection of AEs from organizational source documents was necessary to build an understanding of the degree of overlap between computational methodologies. Commonalities have arisen between the ICD codes coming from government bodies The Centers for Medicare and Medicaid Services (CMS) and PSOs (AHRQ). AEs are detected for Patient Safety Indicators (PSI) coming from AHRQ and Human Acquired Conditions (HAC) coming from CMS.

The manual and hybrid approaches to AE detection were extracted from the organization website sources. These cannot be compared directly with the computational methods in terms of data points due to the incorporation of human judgment. The most effective method with respect to efficiency as well as thoroughness is the hybrid approach. Together, review of medical records with computerized monitoring capture conditions that are associated with more preventable and potential AEs than any singular method. [4; 6; 9]

The sources used for these algorithms are (a) CMS, hospital-acquired conditions, (b) IHI, Global Trigger Tool (c) The Agency for Healthcare Research and Quality (AHRQ, PSI), (d) The Joint Commission (TJC, Sentinel Event definitions) and (e) The National Quality Forum (NQF, serious reportable event (SRE) definitions).

3. Results

Both the CMS HAC codes and the AHRQ PSI rates use ICD codes to detect patient harm. As shown in Figure 1 - 5,702,505 ICD codes are used, and 70,384 are shared. AHRQ uses a large portion of the CMS set plus a great deal more.

Figure 1. AHRQ and CMS detections methods which use ICD codes exclusively.

This large overlap exists due to the use of the Medicare Severity Diagnosis Related Group (MS-DRG) system for financial considerations by the Centers for Medicare and Medicaid Services. This system, in effect, determines the definition of an AE by associating payment penalties with the code combinations that represent harm conditions. The idea of patient safety and the prevention of AEs was the impetus for the MS-DRG

system. That being the case, any computational AE detection methodology in the US will need to also incorporate information from this system.

The AE detection matrix shown in Table 2 classifies rule-based algorithms according to the WHO Patient Safety Conceptual Framework. The WHO incident types are in the leftmost column. The binary patient outcome severity, listed as present or not, is across the top. Both CMS and AHRQ use the MS-DRG system which provides grouping information about severity of an inpatient stay in order to facilitate payment for services. The methodology used in detection is the column title in Table 2 listing the spectrum of methodologies in

Table 2. Computational AE Detection Matrix

Level of Harm Specified		No	Yes		
		EHR Data	EHR Data	Trigger w/ MRR	Observation or MRR
WHO Incident Categories	Behavior				NQF/TJC
	Blood/Blood Products		AHRQ/CMS	IHI	NQF/TJC
	Clinical Administration	AHRQ		IHI	NQF/TJC
	Clinical Process/Procedure	AHRQ	AHRQ/CMS	IHI	NQF/TJC
	Healthcare Associated		AHRQ/CMS	IHI	NQF
	Infection				
	Infrastructure/Building/Fixtures				NQF
	Medical Device/Equipment				NQF
	Medication/IV Fluids			IHI	NQF
	Oxygen/Gas/Vapor			IHI	NQF
	Patient Accidents		AHRQ/CMS	IHI	NQF/TJC

Increasingly difficult and time consuming to complete → practice from completely computational to completely manual.

4. Discussion

This work lays out detection strategies currently in use against an international conceptual framework of AEs, thereby exposing the sparseness of computational solutions in today’s healthcare environment. Each of the fundamental patient safety events in the framework has many subtypes, and out of these 10 categories only 5 are computationally implemented, and one of these doesn’t indicate severity. That leaves half of AE types to voluntary reporting and record review with no external means of being discovered.

Moreover, the computationally implemented detection algorithms rely on coded administrative data. There are concerns about accuracy in this type of data because not all cases of a complication will be captured, leading to both false positives and negatives. Lastly, data quality is a problem in any data source and missing information is the most prominent issue in healthcare data resulting in codes that may not fully reflect the clinical case.[2]

While gaps exist in computational methods, there is good coverage in the application of medical record review. This approach addresses the false positive and false negative concerns but it is intensely laborious and not practical for truly safeguarding patients. The combination of review using a data-driven trigger tool approach has potential as well but is not yet in common practice due to the complexity of the process. [12]

5. Conclusion

Harms caused during healthcare encounters are ubiquitous and occur at an alarming rate and building a complete set of computational detection methodologies in the AE space is urgently needed to address the problem. This is a many-dimensional problem due to multiple organizations, terminologies, detection methodologies and levels of harm. The matrix of patient safety events developed in this study and the resulting synthesis of associated detection algorithms provides a clear picture of areas where coverage gaps exist in AE detection.

^c *IMAGE Information Systems Europe, Rostock*

Abstract. Iodine-containing contrast agents (CA) are important for enhanced image contrast in CT imaging especially in CT angiography (CTA). CA however poses a risk to the patient since it can e.g. harm the kidneys. In clinical routine often a standard dose is applied that does not take differences between individual patients into account. We propose a method that as a preliminary stage determines excessive image contrast and CA overdosing by assessing the image contrast in CTA images obtained with the ulrich medical CT motion contrast media injector with RIS/PACS interface. A resulting CA dose recommendation is linked to a set of clinical parameters collected for each assessed patient. We used the established data set to implement an automatic classification for individual CA dose adjustment. The classification determines similar cases of new patients to take on the associated CA dose adjustment recommendation. The computation of similar patient data is based on the previously collected patient-individual parameters. The study shows that as basis for a recommendations the largest proportion of patients receive too much CA. A first evaluation of the automatic classification showed an overall error rate of 22% to recognize the correct class for CA dose adjustments using a k-NN-Classifer and a leave-one-out method. The classification's positive predictive value for correctly assigning a CA overdosing was 85.71%.

Keywords. CT Angiography, Contrast Agent, Personal Health Care

1. Introduction

Radiological examinations using contrast agents (CA) belong to the basic methods of image diagnostics and interventional therapy. CA used in CT angiography (CTA) gains the contrast enhancing ability through the contained iodine. Iodine-containing CA is however known for being harmful to the renal system with contrast-induced nephropathy being the third leading cause of hospital acquired acute renal failure [1]. However, a standard CA dose is administered to patients in clinical practice. A few methods were proposed to simulate the CA flow based on hemodynamic models [2, 3] that consider

¹ Marja Fleitmann, Institute of Medical Informatics, University of Lübeck, Ratzeburger Allee 160, 23562 Lübeck, Germany; E-mail: fleitmann@imi.uni-luebeck.de.

physiological parameters of individual patients. Nevertheless, the focus there is on the optimization of the CTA scan and not on the determination of a patient-individual CA dose. In [4] a method was proposed to adjust the CA dose based on the patient's body weight and the CT's tube potential. In our approach we propose a method to perform an automatic quality assessment of CTA data (Fig. 1 (blue box)) as a ground truth for CA dose adjustment recommendations for individual patients. Similar to [5, 6] case-based reasoning a Nearest-Neighbor approach is applied, since it showed convincing results in tasks with medical backgrounds and is transparent to a high degree. The automatic classification based on the k-NN uses a multitude of patient-individual parameters to determine the most similar already assessed patient data for a particular case and takes over the corresponding CA dose adjustment recommendation (Fig. 1 (yellow box)).

Figure 1. Quality assessment (blue box) and automatic classification (yellow box).

2. Study

The required CTA data is sourced from a study at the radiology department of the UKSH Lübeck. The goal of the acquiring stage is to collect 400 CTA data sets evenly subdivided into four scan protocols: aortic angiography, pulmonary angiography, pelvic-leg angiography and abdomen angiography. In addition, a multitude of patient-individual parameters are collected. These include parameters like age and height, laboratory parameters (e.g. creatine content) and non-invasive physiological parameters (e.g. blood pressure). To this state 226 CTAs featuring 75 aortic angiographies as the largest share were transferred. Therefore, in this paper we focused on the analysis of CTA data with the aortic scan protocol.

3. Methods

3.1 Quality Assessment of Image Contrast

To enable CA dose adjustments an automatic quality assessment of existing CTA images is implemented. The image contrast is assessed based on selected regions of interest (ROI) in diagnostically relevant locations affected by the CA. The assessment serves as a classification implying whether the applied CA dose is optimal or can be decreased. Three ROIs for each aortic CTA image are evaluated and were defined with the aid of radiological experts:

- ROI 1: Aorta, level: pulmonary artery bifurcation
- ROI 2: Aorta, level: front or lateral outflows of the aorta respectively

- ROI 3: Vessels of the periphery, level: last slice of CTA image

At first the medical practitioner must choose a slice of interest (SOI) for each ROI. Then, an algorithm is implemented to automatically detect the aorta and the peripheral vessels in the SOIs, respectively. To locate the aorta for ROI 1 and 2 an algorithm based on the Circle Hough Transformation (CHT) [7] was used. Based on the resulting Hough space we made the empirical decision to consider the six most probable circles. Because there are more circular shaped structures e.g. the vertebral body, a cost function was implemented similar to [8] to identify the aorta. The cost function assesses the variance, differences in radii and distances of the centers of multiple consecutive circles positioned in adjacent axial slices with a dynamic programming approach. The radius of the starting circle that accumulates the lowest costs is decreased by four pixels to evade calcifications and is declared as the ROI. For detection of ROI 3 the vesselness filter by [9] is applied to the last four slices of the CTA Image to mark the peripheral vessels. The vesselness filter can extract bright lines in 3D based on the Hessian Matrix and their eigenvalues. To remove partially segmented bone structures and calcifications a thresholding with the values [660, 3100] Hounsfield units (HU) was applied to the last slice of the CTA image and subtracted from the corresponding filtered slice to determine the ROI 3. Each ROI is then assigned a category from Tab. 1 with respect to the mean HU value of the particular ROI. The thresholds for the target area were similarly chosen to [10].

Table 1. Definition of the categories of image contrast. The range refers to the mean HU value in the ROI.

Category	Range [HU]	Definition
A	≤ 180	HU value too low
B	181 – 240	Lower tolerance area
C	241 – 300	Target area
D	301 – 360	Upper tolerance
E	>360	area Excessive HU value

Aided by radiological experts rules were formulated to describe the image quality as ground truth for the automatic classification. Applying the rules to the combination of the three ROIs results in one of the three possible classes from Tab. 2.

Table 2. The quality assessment results in one of the following classes and recommendations.

Class	Definition	Rule
1	Image contrast insufficient	At least one ROI is in category A
2	Optimal CA dose	Left over combinations
3	Decrease CA dose	At least one ROI is in category E, the two remaining are at least in category D

3.2 Automatic Classification

The main objective of our project is to enable patient-individual adjustments of the CA dose based on the previously classified CTA data. As a mean to achieve this a k-Nearest Neighbor classification was implemented as a first approach which is suitable if only small training sets are available. The k-NN classification identifies the *k* most similar already classified patient data. The according class is then adopted using majority vote and the recommendation for the dose adjustment can be applied. As features nine clinical parameters were considered based on their previously assessment in literature [2]: age, weight, height, body mass index (BMI), gender, glomerular filtration rate (GFR), ankle brachial index (ABI), oxygen saturation and blood pressure (systolic). For gender we assumed a non-ordinal distribution however further possibilities will be considered.

4. Experiments and Results

4.1 Data

For our experiment we used 75 CTA volumes scanned with an aortic angiography protocol. The CA was administered with a programmed injection rate of 5 ml/s.

4.2 Quality Assessment – Experiments and Evaluation

To test the algorithm's ability to locate the aorta in the selected slice the number of cases where the aorta was manually corrected was considered. The same approach was used to evaluate the vesselness filter to determine ROI 3.

4.3 Quality Assessment – Results

69 cases were processed successfully. The aorta was located correctly in 71.01 % cases. The vesselness filter was corrected in 50.72 % cases. Using the definition of the rules six CTA volumes were assigned to class one, 18 to class 2 and 45 to class 3. As a first insight the quality assessment confirms that there is a CA overdosing in clinical routine examinations. The algorithm proved to be successful for detecting the aorta rarely resulting in failures mostly when confronted with major aortic deformations and dissections (s. Fig. 2). The correction rate of the vesselness filter for ROI 3 was rather high but given the variance in the CTA data, the smallness of the peripheral vessels and the high effort caused by manually determining the vessels, the use of the filter was still rated as a success.

Figure 2. Images of the found aorta and peripheral vessels (red) and the corrections (green) respectively.

4.4 Automatic Classification – Experiments and Evaluation

For the k-NN classification all 2^9-1 combinations of normalized clinical parameters were tested with $k \in [1, 3, 5, 7]$. We used leave-one-out validation to evaluate each classifier resulting in a failure rate. In addition, the positive predictive value for classifying a CA overdose was determined. The Euclidean and the Mahalanobis metric were used as distance measures.

4.5 Automatic Classification – Results

The lowest overall failure rate was 22 % meaning that in 47 cases the determined class matched the prior classification. The rate was achieved with the Mahalanobis metric as

the distance measure and $k = 3$ neighbors. The optimal combination of clinical parameters used was: ABI, height, BMI, oxygen saturation and blood pressure.

Considering the clinical parameters some (BMI, height) were expected due to their examined correlations with contrast enhancement in literature [2, 4]. Others like ABI, oxygen saturation and blood pressure can be considered as indicators for the vessel condition and therefore influence the CA flow and distort the CTA scan. The positive predictive value of the automatic classification after merging class 1 and 2 to correctly assign class 3 (Tab.2), which is crucial for dose reductions in the use case is 85.71 % and showed a rather high prediction quality.

5. Discussion and Conclusion

In this paper we presented a method for an automatic quality assessment of CA-induced contrast enhancement in CTA images with an application for patient-individual dose adjustment. By considering clinical parameters of a new patient the examiners could decrease the CA dose in the use case to lower the risks of CA-induced side effects. While the implemented algorithm is robust for locating the aorta the need of user-determination for the SOI could also be automated. Furthermore, it is debatable how feasible it is to choose the last available slice for the ROI. Therefore, a fixed landmark for the ROI 3 e.g. the aorta femoralis communis will be set. As a next step we will consider deep learning approaches to replace the k-NN classifier for more precise results based on the increased number of patients in our ongoing study. In addition, the presented system will be applied to returning patients for validation.

Continuous Monitoring and Statistical Modelling of Heart Rate Variability

Adina NITULESCU^{a,1}, Mihaela CRISAN-VIDA^a and Lacramioara STOICU-TIVADAR^a

^a*Faculty of Automation, and Computers, University Politehnica of Timisoara, Romania*

Abstract. The paper presents a sensor network system implemented to continuously monitor and detect cardiovascular diseases experienced in patients at high-risk. The device is designed to capture and transmit the ECG signals and pulse to the patient's mobile phone. Later interpretation of the single-lead ECG signals will result into a HRV analysis and heart-rate detection that is compared with the pulse oximeter results for validation. The fastest alert will be issued to doctors, relatives and hospitals, using the proposed data processing algorithm implemented in the patient's mobile phone. The continuous usage of this monitoring system provides an effective, efficient and fast health care service to patients at risk, even if the doctors or relatives are not near the patients.

Keywords. sensor, electrocardiogram, alert, emergency, wavelet transform

1. Introduction

In the past, it was difficult to use sensors and front-end electronics in wearable technology to gather physiological and movement data because of their size. But now, wearable sensors are available at a much lower cost and utilized in digital health monitoring systems with miniature circuits.

Prevention is especially critical for cardiovascular diseases and electrocardiogram (ECG) is the most undisputed and widely accepted tool to detect and diagnose them. Apart from their enormous impact in older people life expectancy, cardiovascular diseases are also the main cause of death for the population among 44 and 64 years and detecting their symptoms in time is critical to avoid irreparable damages or death. Our solution comprises of an integrated system module that captures the physiological ECG and SpO2 data that is measured using a single board computer card, a micro-controller and an e-health sensor platform.

Timely access to emergency cardiac care and survival is partly dependent on early recognition of heart-attack symptoms and immediate action by calling emergency services. In a 2016 study [1], most persons (95%) recognized chest pain as a heart-attack symptom, but only 11% correctly classified all symptoms and knew to call 1-1-2 when someone was having a heart-attack. This proved the need of medical devices that continuously monitor and record the physiological parameters of patients outside the clinical environment as part of a care pathway.

[2] presents a mobile healthcare application for self-diabetes management. The application synchronizes data with hospital's EMR database to provide accurate data.

[3] presents a mobile app integrated into a hospital workflow to achieve medication list portability via Fast Healthcare Interoperability Resources.

[4] presents FHIRbox which is a distributed system under development by the authors of the paper for integrating data from various diagnosis devices and uses FHIR for exchanging clinical information.

Still an important issue is the continuity of healthcare, the communication standards will lead to a better patient healthcare activity. The exchange of information between different medical unit's information systems and devices, and understanding each other means that the interoperability request is satisfied. In this paper the standard which will be used is HL7 Fast Healthcare Interoperability Resources (FHIR) [5]. This standard provides access to medical data via a RESTful API which uses XML and JSON. The benefits of using FHIR are: real-time, query-able, patient – centric interface to EHR Resources; HTTP/REST greatly strengthens interoperability, the specification of this standard provides all the needed data and modern code libraries and architecture.

2. System description

The system is designed to capture the physiological ECG signals and detect the heart-rate using wavelet decomposition and fixed thresholding of wavelet coefficients. The following components were integrated in the system capturing module:

- Pulse Oximeter module, designed to capture patient-specific pulse and saturation oxygen signals, digitize and send them to the e-Health Sensor shield.
- ECG electrodes, diagnostic tools that are routinely used to assess the electrical and muscular functions of the heart further useful in the diagnosis of a myriad of cardiac pathologies.
- GSM shield: In order to make calls on threshold events, the system includes a GSM shield for the Arduino Uno, connected directly throughout the pins.
- Arduino + Raspberry Pi module, connected by using the I2C communication protocol.

The captured data is further processed for diagnosis, treatment or both. It also enables the patient to be more engaged and auto-monitor their health status by regularly or continuously checking the values of the vital parameter stated above. The data collected is stored in a database which further can be accessed by an API for creating a file in the HL7 FHIR standard format. The API used in this system is Azure API for FHIR [6]. The data sent using FHIR for our particular case is accessed by the Obstetrics-Gynecology Department Information System previously developed and in use by the medical staff [7]. The Obstetrics-Gynecology Department Information System (OGD IS) was developed using Visual Studio.NET 2015, ASP.NET pages and C# language, it is a responsive web application, and may be accessed by the doctors using a tablet. OGD IS has a statistical component which allows the medical staff tracking of health parameters and draw different charts related to treatments, or IoT systems.

Figure 1 presents the general architecture of the solution presented in this paper.

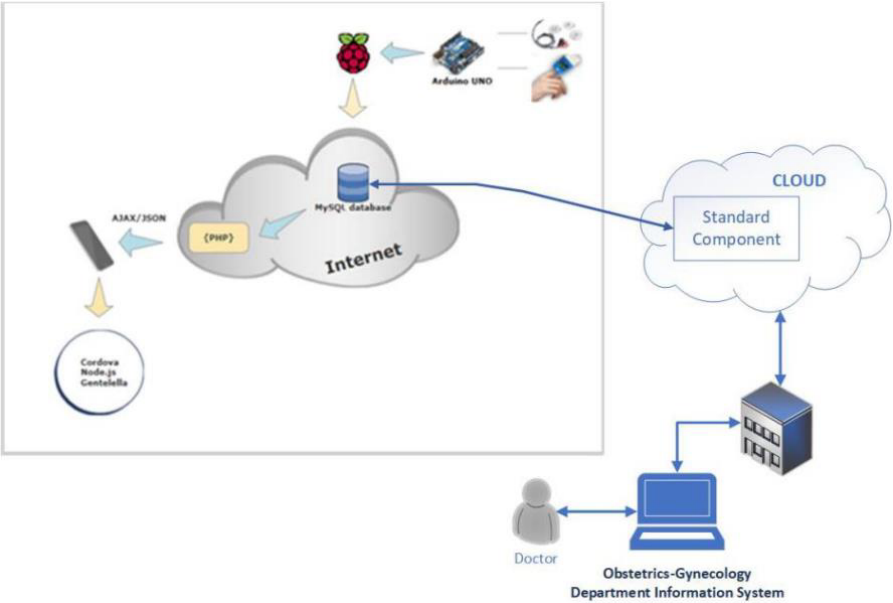

Figure 1. Overview of the system

2.1. Mobile application

The client mobile application is designed specifically to be accessed from personal smart-phones and it permanently displays the patient status and time evolution illustrated by graphs and alarms in case of threshold events. The application is built using PHP, HTML, Ajax and JavaScript technologies. This client application can be easily accessed from mobile Android devices to provide healthcare professionals with the ability to check their patients' status when not near them, and can receive alarms when a patient's condition is critical.

In figure 2 we present the mobile application user interface, called RpiHm (Raspberry Heart Monitor) build using Apache Cordova, an open-source mobile development framework. The template used is Gentelella, a free to use Bootstrap admin template. It uses Bootstrap 3 styles along with a variety of powerful jQuery plugins and tools to develop a powerful framework for creating admin panels and back-end dashboards.

The app can be downloaded on the phone and used by both the patient and the physician for continuous monitoring. It displays information regarding the beats-per-minute, the oxygen saturation (SpO2) and a graph. Upon launching, the ECG graph begins collecting data from the MySQL database and constructs the waveform.

3. Statistical analysis

By loading the data set into Tableau, we can perform a statistical analysis and derive models and patterns in our values. In Figure 3 we can see the preprocessed ECG data that is being used to detect the heart-beat rate. The detection is performed by using discrete wavelet transform (DWT) in order to obtain the amplitude and duration of the

characteristic ECG waves and to determine the RR interval time series. The programming language used for the heart-rate variability (HRV) analysis is R, a free software environment for statistical computing and graphics.

Figure 2. Mobile app

Figure 3. Preprocessed ECG data

By further refining, we conclude that roughly all the values from our dataset are situated in the 70-80 bpm interval, a healthy distribution since any resting value outside this range can be considered a threat. We further want to predict the probability of having a heart disease and we compare the accuracy of three different algorithms: k-nearest neighbors, logistic regression and decision trees by using 230 observations in the training set and 40 in the test set. The accuracy scores for the selected algorithms are very similar and are more or less 85%. After plotting the ROC curves and calculating the area under the curve, we can finally conclude that the logistic model is the most accurate for our study set.

Figure 4. Comparison of ROC curves

4. Conclusions

Since the monitoring of hospitalized patients is currently being carried out only in critical cases, especially in intensive care units, using inflexible and costly systems, it has been considered useful to the medical world to demonstrate the construction of a system that highlights the technological advance in recent years in the field of monitoring the heart health, bringing benefits in terms of cost, flexibility, interoperability and usability. In order to meet these factors, it was chosen to monitor the heart's activity redundantly to enhance patients' comfort, provide a reliable set of data and building an accessible client application from mobile devices for quasi-real-time viewing of the patients' situation. The doctors and caregivers monitor the patient in real time using the data received through the server. Ensuring the interoperability between the mobile application and other medical units using FHIR, as in our particular system is presented the communication with an Obstetrics-Gynecology Department, improves the patient health and the doctor has a better support for a better treatment, due to continuity of healthcare records.

Abstract. Analysis of consumptions has proved a misuse of antibiotics, despite the existence of national requirements. To be able to compute drugs consumption quantities of highly heterogeneous drugs expressed in various doses units, the World Health Organization has defined a defined daily dose. A methodology has been also defined from previous work to compute manually the drugs consumptions in daily defined dose. We automated this methodology by using data fusion on data retrieved from different sources including a French public database and the World Health Organization website. Evaluation proved the efficiency of the approach, except for inconsistency cases. We identified these cases and proposed a solution to avoid them.

Keywords. Drug database, Health Information Interoperability, Automatic data processing, Drug misuse

1. Introduction

French authorities in public health study and publish regularly results about antibiotics consumption in France and in the world [1]. More generally, drug consumption trends are observed [2]. Due to a misuse of antibiotics, it is thought that “Antimicrobial resistance could become one of the leading causes of death in the world” [3]. To obtain these results it is necessary to compute automatically measures reflecting the consumption of antibiotics. World Health Organization (WHO) has defined a unit to express to consumptions, called daily defined dose (DDD). Drug Defined Dose is defined by WHO as “The assumed average maintenance dose per day for a drug used for its main indication in adults.” [4]. It was first introduced by S. Natsch et al [5]. It was observed that, despite the existence of national requirements, hospital antibiotic stewardship programs are not fully implemented in France [6] Hence, it is necessary to automate the computation of the drugs consumption, and more precisely antibiotics consumption, in DDD using data and information stored in the clinical information systems.

¹ Corresponding Author, E-mail: adrien.ugon@esiee.fr.

The ATC (Anatomical Therapeutic Chemical) Classification system hierarchically classifies therapeutic drugs into 5-level groups, considering the organ or system on which they act and their chemical, pharmacological and therapeutic properties. Each group is identified by a code.

WHO provides a DDD, for each ATC code, and administration route, and sometimes pharmaceutical form, as a dose expressed with a value and a unit. They can be retrieved from a website using text mining methods [7]. Hence, the computation of drug consumption quantity can be considered as a unit conversion. Methodology to measure antibiotic consumption has been proposed in previous work [8] but needs to be automated.

Drug information is provided by French public database [9] under heterogeneous formats. Structured information are provided in text files following the tabula separated values format. Information on specialties is given in a first file called *CIS_bdpm.txt*. Each specialty is identified by a CIS (French for “Specialty Identifier Code”) code, and described with the name, the administration route, or the pharmaceutical form and other administrative information about the specialty. Each specialty can be sold in different presentations, each being identified by a CIP (French for “Presentation Identifier Code”). All presentations are provided in a file called *CIS_CIP_bdpm.txt*, providing CIP code, CIS code, presentation name, price and other administrative information about presentation. A third file, called *CIS_COMPO_bdpm.txt* provides information about the substances that are part of a medicinal product, among which the name of the substance, the dose, the nature (active substance or therapeutic fraction). In addition of this information, HTML pages provide other textual information that can be parsed with text mining method. The ATC Code needs to be retrieved from these HTML pages.

This paper aims at designing a tool to automate the computation of the drugs consumption in DDD using information provided by a French public drug database. Section 2 will describe the methods. Results will be provided in section 3. Finally a discussion will be proposed in section 4.

2. Methods

Our approach is based on data fusion. It has been proved that symbolic approaches are efficient to fuse heterogeneous, and eventually multimodal data coming from various scattered sources [10]. The system is composed of two consecutive steps: (1) data retrieval (2) data fusion.

2.1. Data retrieval

To be able to compute the consumptions in DDD, it is necessary to retrieve all necessary data. In the clinical information systems, consumed drugs are identified by their CIP code, which is given in the *CIS_CIP_bdpm.txt* file. Then, we need to know the dose of all substances that compose the drug, which is provided in the *CIS_COMPO_bdpm.txt* file. The link between the two files is the CIS, identifying a specialty, provided in the two files. With this information, from these two files, it is thus possible to retrieve the dose of all substances that compose a drug.

To retrieve the DDD defined by the WHO, it is necessary to have the administration route, which is provided in the *CIS_bdpm.txt* file given the CIS Code. The ATC Code can be retrieved from the HTML page, given a CIS Code and using a regular expression. Because of errors in the ATC Code – some of them used the “O” character instead of the

“0” number – it was necessary to use an adapted regular expression to find all ATC codes for a given CIS code. Hence, we used the following regular expression: “[A-Za-z][0-9O]{2}[A-Za-z]{2}[0-9O]{2}”. It is then possible to retrieve the DDD value and units by parsing the ATC/DDD Web page for a given ATC Code.

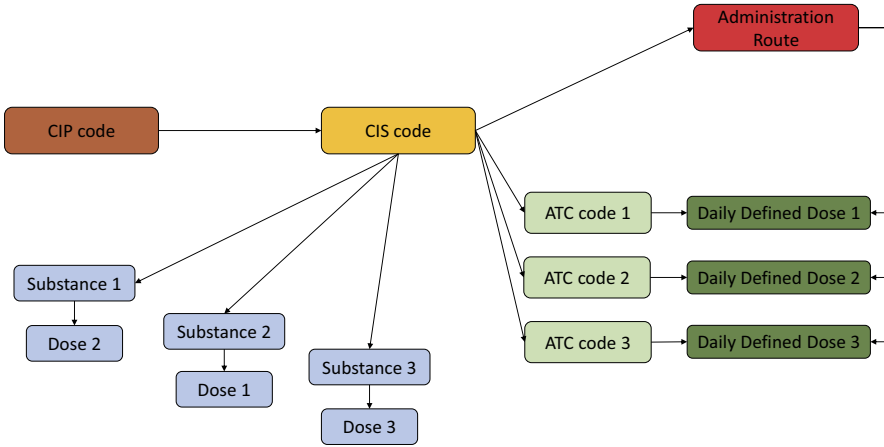

Figure 1. Data dependencies

Figure 1 shows the relationships between the different required data. In a yellow rectangle is represented the CIS code, which is the key data allowing to link all other data. In a brown rectangle is represented the data provided in the *CIS_CIP_bdpm.txt* file; in blue rectangles are represented data provided by *CIS_COMPO_bdpm.txt* file; in red rectangle is represented the data provided by *CIS_bdpm.txt* file; in pale green rectangle is represented the data provided by HTML pages of the public drug database; in forest green is represented the data provided in the WHO ATC/DDD Webpage.

2.2. Data fusion

Respecting the principles of high-abstraction-level symbolic fusion [11], all data is represented as a list of multimodal data, indexed by an identifying code. Fusion strategies are defined to fuse data considering the relationships pointed out in Figure 1.

Figure 2. High-abstraction-level fusion strategies

Figure 2 shows how high-abstraction-level fusion strategies are defined considering the data model presented in Figure 1. Multimodal data is represented by conceptual

graphs allowing the fusion. By applying fusion strategies, we can enrich information about a medicinal product identified by a CIP code.

Once we have got the DDD provided by the WHO and the dose of all substances of a drug, we are able to compute their value expressed in DDD by dividing each substance dose by each DDD associated with a specialty. As a consequence, one value will be computed for each substance of the drug.

3. Results

The method was applied to the 20 479 drugs, identified by a different CIP code, from the *CIS_CIP_bdpm.txt* file, present in the French public drug database; we were able to compute the dose expressed in DDD for 9 264 of them (45.23 %). We were unable to compute the DDD for 249 drugs for inconsistency reasons which will be discussed in the next section. The main encountered problem was that for 11 027 drugs (53.8%), the DDD was not defined by WHO.

By focusing on antibiotics, we found 966 entities, among which we were able to compute the dose expressed in DDD for 780 (80.8%) of them.

4. Discussion

Several inconsistencies were observed in data and information provided by the French drug public database, making sometimes impossible to compute the DDD.

First, we observed missing data. Although information was provided for a CIP code, information about corresponding CIS code was missing, either about the composition of the drug, or about the administration route. This should be solved by checking the completeness of the information provided in the database.

Second, only one ATC Code is given – at most – on the web page of the French public drug database, which does not reflect some cases where a drug can have several ATC codes. This is the case, for instance, of the prednisolone, which has seven ATC codes; the only that can be retrieved from the web page is H02AB06. This can be solved by adding all the ATC codes to the structured files.

Third, as already mentioned, there can be errors in the ATC code, which can be missing, or can be shorter than expected, or containing spaces and containing the “O” character instead of a “0” number. For these reasons, text mining methods using a regular expression are not efficient to retrieve all ATC codes. This should be solved by providing a clean value of the ATC codes in the structured files.

Fourth, there is no alignment of administration routes representation in the drug database and in the WHO ATC/DDD webpage. To be able to compute the consumption in DDD, it is necessary, in a preliminary step, to align manually the different values used in the two sources. Standardizing the expression of administration routes would allow to prevent this issue.

Fifth, doses are sometimes expressed under a form that is impossible to process automatically. For instance, doses like “2ch to 30ch and 4dh to 60dh”, or “75 mg equivalent to 69,6mg of risedronic acid” cannot be processed automatically.

Sixth, sometimes substance doses and WHO DDD are expressed in incompatible units : micrograms and Thousand Units, milliliters and milligrams. Constraints on the

dose data format, combining a numeric value to a unit would allow to avoid the two last presented issues.

Finally, there exists some ATC codes without any DDD by the WHO. For instance, “J01DA33”, “G04CA05” or “R02AA19” have no DDD by WHO.

^c*Data-Integration-Center, Faculty of Medicine, Justus-Liebig-University, Giessen, Germany*

Abstract. Data integration is an important task in medical informatics and highly impacts the gain out of existing health information data. These tasks are using implemented as extract transform and load processes. By introducing HL7 FHIR as an intermediate format, our aim was to integrate heterogeneous data from a German pulmonary hypertension registry into an OMOP Common Data Model. First, domain knowledge experts defined a common parameter set, which was subsequently mapped to standardized terminologies like LOINC or SNOMED-CT. Data was extracted as HL7 FHIR Bundle to be transformed to OMOP CDM by using XSLT. We successfully transformed the majority of data elements to the OMOP CDM in a feasible time.

Keywords. ETL, OMOP, HL7 FHIR, LOINC, SNOMED-CT

1. Introduction

International collaborative research faces a variety of challenges. One includes integrating data from different heterogeneous data sources into a data repository or data registry. Such registries can serve a lot of different purposes such as drug safety analysis [1], longitudinal analysis of certain cohorts [2] or as in our, and many other cases [3] a disease specific registry to promote research in that field. As part of the Pulmonary Vascular Research Institute, a collaboration of healthcare professionals and researchers working in the field of pulmonary hypertension (PH), an international PH registry/data repository needs to be established.

We chose the OHDSI OMOP Common Data Model [1] to be the foundation of this registry. The OMOP CDM is a database specification, based on standardized vocabularies like SNOMED-CT, LOINC or RxNorm, with the aim to provide an analytic-friendly non-complex representation of medical data [1].

To populate a registry with data from existing databases, usually, Extract-Transform-Load tools (ETL) are used to transform and transfer data to the target schema. Popular tools in this regard are Talend Open Studio or Pentaho, which are used to define the ETL process as a dataflow from source to target system. However, by using such software a complete ETL process needs to be implemented for each source separately. This is also the recommended way of designing ETL processes for the OMOP CDM. Because we want to connect multiple heterogeneous databases, a common parameter set was predefined. We plan to use HL7 FHIR [4] as an intermediate format for the local data extraction. The FHIR resource will be fed into an XSLT processor to generate CSV files in the OMOP schema. Similar international and national approaches using intermediate formats or HL7 FHIR together with OMOP CDM have led to good results [5–7].

Therefore, our aim is to evaluate the feasibility of HL7 FHIR Bundle and XSLT as a generic ETL process to populate an OMOP CDM. Feasibility will be assessed by the computation time and coverage of source data in the target CDM.

2. Method

2.1. Common data set

To integrate data from multiple registries into a single data warehouse, a common data set is needed. A meeting of domain experts from two large PH registries from both the UK and Germany was scheduled to discuss all data items and produce a common data set definition. In a second step, this data set is annotated with international standard terminology (LOINC, SNOMED-CT, etc.) by documentation experts.

2.2. Source data

As source data, we used a German PH registry database. Its data is stored in a Microsoft Access database with 22 proprietary tables and 18 user forms. Additionally, two EXCEL sheets are used to collect data about specimen and echocardiography. All tables are exported to CSV format using MS Access’s standard export functionality. For ETL-preparation, we used HStream-import to convert the proprietary CSV files to a standard FHIR Bundle collection. For this purpose, an XML configuration file is written which includes mapping of source field names to standard terminology as defined by the common data set. The resulting HL7 FHIR Bundle resource contains Patient, Encounter and Observation resources and conforms to the latest FHIR standard 4.1.0 [4]. An example of the Bundle structure containing the source data is depicted in Figure 1.

Figure 1. Example FHIR Bundle structure of provided input data

2.3. Mapping to OMOP domains

The OMOP CDM splits data into different domains depending on their scope. Condition, Drug, Procedure, Measurement are common medical domains, which are mapped to separate tables in the OMOP CDM. We used Athena [8] to browse the complete OMOP vocabularies to find the correct target table for the data elements of our defined data set. We did so by searching for the respective SNOMED-CT, LOINC or ATC code and retrieving the OMOP domain of the resulting concepts, as well as the concept ids.

2.4. Extending OMOP vocabularies

There are many subtypes of pulmonary hypertension depending on the etiology or comorbidities of the patient. Those subtypes are classified using the clinical classification of the World Symposium on Pulmonary Hypertension of 2013, which is also referred to as PH Nice Classification [9]. Since the Nice classification is not part of the standardized vocabularies already included to OMOP, we had to add it manually.

By using the hierarchical classification and the ER model of the OMOP standardized vocabularies [10], we generated CSV files to bulk load the Nice classification to OMOP.

2.5. Data transformation using XSLT and XPath

To transform the source data, provided as HL7 FHIR Bundle, to the OMOP schema we used XSLT (v2.0) [11] and XPath (v2.0) [12] to generate CSV for each used OMOP target table. The resulting CSV files contain all required information for the respective table, e.g. Measurement or Patient.

3. Results

3.1. Mapping to standard terminology

The predefined common dataset consists of 141 distinct data elements all represented by a specific code. Out of the 141 elements, 36 have been mapped to SNOMED-CT, 38 to LOINC, 27 to ATC and one to ICD-10. 27 of the remaining 39 data elements belong to the PH Nice classification, while no standard code was found for 12 parameters.

3.2. Algorithm

The transformation is split up into different files, one for each table that will be populated. Currently our approach populates the following OMOP tables with all required fields: *PERSON*, *OBSERVATION_PERIOD*, *CONDITION_OCCURRENCE*, *DRUG_EXPOSURE*, *PROCEDURE_OCCURRENCE*, *OBSERVATION* and *VISIT_OCCURRENCE*

The transformation structure is in principle the same for each table. A generic XSLT template is defined, to generate one row for each entry to the respective table. This generic template also extracts metadata about the entry like the date time or references to patients or encounters. Additionally, we defined parameter-specific templates, which map one parameter to its correct concept id in OMOP. Those parameter-specific

templates call the generic template with the correct parameter specific data like concept id, status ids or type ids for the respective parameter.

The resulting CSV files are then bulk loaded to the database. A schematic illustration of the ETL process is shown in Figure 2.

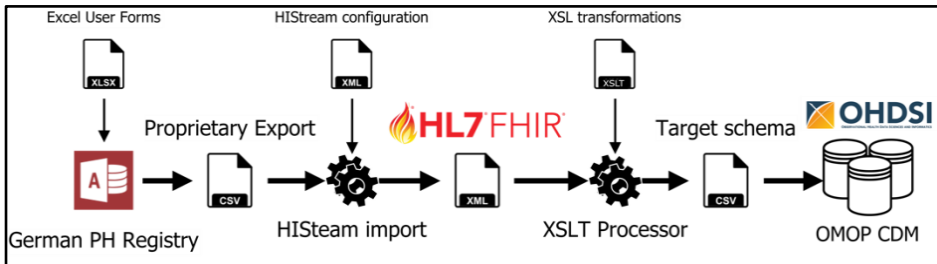

Figure 2. Schematic illustration of ETL process, showing involved software, including configurations and temporary result files

3.3. Transformation results and performance

Except for the 12 data elements of the common data set, where no standard concept in the standardized vocabularies could be found, every element was successfully mapped to the OMOP domains resulting in an overall coverage of about 91.5 %. We applied for new codes within LOINC for five data elements [13]. Additionally, we added 34 new concepts, 54 concept relationships and 68 concept ancestor entries to the vocabularies and therefore achieved 100 % coverage of the PH Nice classification in OMOP.

In total, data of 3,887 patients was transformed to OMOP in 15 minutes and 29 seconds using Saxon-HE v9.9.1 XSLT processor (on Intel Core i7-8550U with 256 GB SSD). To populate all required fields, we assigned default values for the parameters, which were not available in the source data. Those fields were for example: *visit_type*, *admitted_from*, *discharged_to* and others. In addition, fields like ethnicity and race have been set to default values for the first prototype, but those will be correctly mapped in the future as well.

4. Discussion

Based on the achieved results we conclude the feasibility for HL7 FHIR Bundle and XSLT as part of a generic ETL process. The majority of data elements were successfully transformed to the target scheme in reasonable time. Additionally, the customization of the available ETL process to connect new source databases reduces to only adjusting the data extraction process and HISstream configuration to provide data as HL7 FHIR Bundle. Therefore, providing a HL7 FHIR export for a local data source can increase interoperability of the included data, not only for data warehousing, but also for communication with other systems.

Limitations of this work include the necessary synchronization between HISstream configuration and XSL transformations in order to transform all available data elements to OMOP. Additionally, the mapping of standard concepts is currently hard coded, by leveraging the rich vocabularies provided as CSV the mapping can be designed in a more

generic way. We also plan to reduce the computational time, even though 15 minutes for the transformation is already feasible because data will only be loaded periodically.

Abstract. This paper discusses the topic of data quality, which concerns the global research and business community and constitutes a challenging task. The data quality prerequisite becomes even more critical when it pertains to critical and sensitive data, such as the healthcare domain data. To begin with, the paper outlines the basic definitions and concepts of data quality and its dimensions. The related research work on data quality assessment is presented and our approach for data quality assurance is introduced. This approach is implemented in our designed cloud platform, called MODELHealth, which is intended for supporting clinical work and administrative decision-making process.

Keywords. data quality, health data, ehr, quality assurance

1. Introduction

Today's world is entirely data-driven. Enormous amounts of data are generated at every point of interaction. Therefore, how this data can be used effectively is a matter of great importance. For this data to be utilizable, they have to meet some requirements and be reliable, up-to-date, and of high quality. Thus, data quality is one of the biggest challenges in the digital world. The high volume and complexity of data collected across multiple sources create an enormous task in terms of data quality management. It is essential to mention that the issues in data quality can directly affect analytics and decision-making.

For these reasons, data quality is recognized as widely considered to be a critical factor, especially in the healthcare sector. This paper outlines the basic definitions and concepts of data quality and proposes a new approach for data quality assurance.

2. Quality of Health data

2.1. Data Quality Definition and dimensions

Data are real-world objects, with the property of storing, retrieving and elaborating through an algorithmic process and can be communicated between two entities. **Data quality** has a distinct definition in various fields and periods. Multiple definitions of data quality have been proposed, but data is generally considered high quality if **they are fit “for intended uses in operations, decision making, and planning”** [1] or, more generally, **“for the purposes data consumers want to apply them”** [2]. Indeed, the quality of data is critical for improvement process activities, and it can be addressed in various fields inclusive of finance, statistics, computer science, and medicine.

The primary phase in any data quality process is to define the properties of data quality; those properties are defined as data quality dimensions (DQDs). A **Data Quality Dimension** is a term used to define a data quality measure that can describe numerous data elements including attribute, record, table, system or more abstract groupings, such as business unit, company or product range [3]. Researchers have recognized various numbers of dimensions for data quality, but the most important are the six following core dimensions: Accuracy, Completeness, Consistency, Timeliness, Uniqueness and Validity.

Accuracy of the data is the degree to which data is correct, reliable and certified. In other words, data are accurate in case of data values stored in the database are equivalent to real-world values. It is a measure of the correctness of the content of the data.

Completeness of the data concerns the extent to which values appear in a dataset. With regard to a separate datum, only two conditions are potential: The attribute under consideration has a value or not.

Suraj Juddoo et al. suggested that the two common most significant DQDs to consider in the context of big datasets for the health domain are accuracy and completeness [4].

Consistency of the data is the extent to which information is presented in the identical format and compatible with previous data.

Timeliness of data regards only the interval between an alteration of a real-world state and the outcoming modification of the information system state. Timeliness has two constituents: age and volatility, which are a measure of how old the information is and a measure of information instability, respectively.

Uniqueness of data determines the extent to which there are no duplicate values.

Validity of data refers to data that have been collected in conformity with any rules or definitions that apply to that data. This will enable benchmarking between organizations and over time.

According to the *“Harmonized Data Quality Assessment Terminology and Framework for the Secondary Use of Electronic Health Record Data”* [5], an initiative aimed at providing a solution to the inconsistency of data quality terminology used throughout the relevant scientific literature, the main proposed categories of healthcare data quality are:

Conformance: The data should be compliant as far as format, relational reference, and computational accuracy are concerned. The subcategories of conformance are:

- **Value Conformance:** Values and format of the data should adhere to all given prespecified data architecture constraints.

- **Relational Conformance:** Data should be consistent with the given structural constraints (nullability, referential integrity, etc.).
- **Computational Conformance:** If there are computed values derived from existing data, they should be correct and consistent between computations based on the same specifications (internal or external programs).

Completeness: In accordance with the respective dimension mentioned above, data should be complete, i.e., conforming to the expected frequencies of every data attribute value presence. In this context, completeness is not concerned with the data values, structure or plausibility.

Plausibility: The data values should be believable/truthful when put in context (other variable values, temporal sequences, state transitions etc.). Plausibility subcategories are:

- **Uniqueness Plausibility:** Objects represented by data should not appear multiple times where duplication is not explicitly justified.
- **Atemporal Plausibility:** Observed data values and/or distributions should agree with domain knowledge, trusted external sources or established “gold standards”.
- **Temporal Plausibility:** Time-dependent variable values should change as expected, taking under consideration established temporal properties.

2.2. Importance of Data Quality in Electronic Health Record

E-health constitutes a recognized term and is close related to the usage of **Electronic Health Records (EHRs)**, so as to achieve adequate communication between healthcare sectors. Specifically, various sources of healthcare data exist, such as the internet, electronic patient records, data analysis tools, communication between health experts and patients, electronic health devices. Data management and analysis tools aim to improve healthcare organizations operation in terms of obtaining useful information and knowledge via conversion of the aforementioned vast resources [6].

It is crucial that the collected data are precise, comprehensive, reliable, comprehensible and available to all stakeholders such as patients, health experts, legal authorities, and government authorities [7]. Therefore, data quality issue constitutes a significant challenge concerning health records and is able to provoke pivotal effects on every health sector operation. A considerable amount of lethal medical errors concerns the result of missing or incomplete data about medication, instructions, and treatment plans [8].

In addition, adequate data quality plays a significant role in the successful implementation of machine learning methods, and it presents one of the significant challenges, especially in the healthcare domain [9], [10]. Poor quality input data are, most of the times, a critical liability in the machine learning process as, in essence, they carry an altered state of the underlying patterns that represent the “truth” of the data, leading to an altered “reality” perceived by the algorithm. It’s self-evident that regarding a learning process, if the foundation -the learning material- is critically impaired, one should not have many expectations of the outcome.

The most common source of data used in machine learning processes of medical significance is operational software systems in clinical environments, mainly EHR transactions. This secondary analysis setting, meaning the use of the data for research analytics, which is not their original purpose of collection, has been researched

extensively towards assessing and dealing with the factors that affect data quality [11]–[13]. It has been found that *“EHR data from clinical settings may be inaccurate, incomplete, transformed in ways that undermine their meaning, unrecoverable for research, of unknown provenance, of insufficient granularity, and incompatible with research protocols”* [11].

3. Health Data Quality in MODELHealth

MODELHealth is a cloud platform that facilitates the application of Machine Learning methods, towards processing health data, in order to support clinical work or/and the administrative decision-making process, in all levels of health services provision. It is a “holistic” approach to the subject of developing and exploiting Machine Learning algorithms. It covers the whole lifecycle of the respective process, from querying, homogenizing, anonymizing and enriching raw data, to the final provision of the resulting algorithms via Application Program Interfaces, in order for them to be consumed by any authorized Information System. For projects like MODELHealth, data retrieval is a critical step, as the raw data that are produced by querying a real-world database need to be handled on various levels for a number of reasons before they end up on the central data repository, in order to participate in the training and validation of machine learning algorithms.

To this end, the ETL (Extract, Transform & Load) mechanism of the MODELHealth platform contains a **dedicated Quality Assurance (QA) module**, as well as an Entity Mapping module that handles ontologies and central database homogeneity and an anonymization module that handles patient privacy and regulatory compliance. Both latter modules lie outside the scope of this text.

Regarding the data quality Assessment, the QA module of the ETL system is capable of performing a number of tests on the incoming data, based on a customizable and extendable rule-set that quantifies data quality in the form of test success-failure percentages. There will be rules covering the whole aforementioned spectrum of healthcare data quality: atemporal completeness, value conformance, and atemporal plausibility. These are the factors that are primarily investigated through data quality checks by the organizations which are currently engaged in data quality assessment [14]. Via centrally defined customizable thresholds for each active rule, the administrators can set the quality tolerance of the data retrieval process, thus controlling the minimum quality requirements of the data that actually make it to the central data repository. This is accomplished by “instructing” the decentralized ETL mechanisms to reject data that do not meet the desired criteria.

More specifically, in order to pursue the quality standards, the developed QA module will be based on the research conducted by Nicole G. Weiskopf et al. [15]. The tool’s core framework takes into account three different forms of data: complete, correct, and current data. Data quality assessment issues diversify from one another forms of data. Furthermore, the operationalization of the above forms varies depending on the three main types of HER data: patients, variables, and time. As a result, the combination of the aforementioned 3x3 elements produces nine constructs that lead to different methodological recommendations, in other words guideline-based best practices, for EHR data quality assessment.

4. Conclusions

This paper has described a spectrum of issues associated with the quality of health-care data. Because contemporary EHR systems suffer from many shortcomings, the medical data that they produce are also often flawed. Data-quality problems can compromise the value of databases for scientific research, quality assessment, public health, and other purposes. Analytical insights in healthcare should always be probed for data quality problems. Also, the value derived from the use of analytics should dictate the requirements of data quality. This is emphasized because most analytical tools assume that the data are of very high quality. Based on this premise, MODELHealth attempts to apply contemporary data quality checks, towards a systematic approach to data quality, in order to ensure a reliable and viable developed asset for healthcare organizations for the holistic implementation of machine learning processes.

Abstract. Sensitive data is normally required to develop rule-based or train machine learning-based models for de-identifying electronic health record (EHR) clinical notes; and this presents important problems for patient privacy. In this study, we add non-sensitive public datasets to EHR training data; (i) scientific medical text and (ii) Wikipedia word vectors. The data, all in Swedish, is used to train a deep learning model using recurrent neural networks. Tests on pseudonymized Swedish EHR clinical notes showed improved precision and recall from 55.62% and 80.02% with the base EHR embedding layer, to 85.01% and 87.15% when Wikipedia word vectors are added. These results suggest that non-sensitive text from the general domain can be used to train robust models for de-identifying Swedish clinical text; and this could be useful in cases where the data is both sensitive and in low-resource languages.

Keywords. EHR, clinical text, de-identification, deep learning, wiki word vectors

1. Introduction

De-identifying health data is an important problem for health data reuse, and the topic has generated significant scholarly interest because of increased use of electronic health records (EHR). Re-use of the data in research could give us unique insights into disease etiology and progression, as well as a greater understanding of patient care processes and pathways. Current de-identification methods rely on sensitive health data for training. This presents a number of data-sensitivity problems, such as when there is need to transfer or adapt the models to new target data. In this study, we investigate the usefulness of non-sensitive training data from the general domain.

Two main approaches have so far been used for de-identification namely, rule-based and machine learning-based methods [1]. Studies show that more successful de-identification systems use a hybrid of both these approaches [2]. On the one hand, rule-based methods can go as far as using name lists from the economy/administration software to match against the clinical text [3]. While this can be an effective solution, it is not robust enough for simple variations or for use outside the specified datasets or organizations, and could entail serious risks to patient privacy. On the other hand, machine

¹Corresponding Author: Taridzo Chomutare; E-mail: firstname.lastname@ehealthresearch.no

learning approaches, while more robust since they learn patterns, instead of matching specific instances, still require a large amount of sensitive data.

Machine learning approaches require a lot of training data or examples to learn from. Creating examples by annotating the data is an expensive proposition because it requires specialist knowledge, and the amounts of data are enormous. Unsupervised methods which can be used to discover discriminating features in new target datasets are emerging. These emerging deep learning architectures do not require any feature engineering to produce state of the art results [4]. So far however, these architectures have only used embeddings from sensitive data or scientific medical publications like PubMed [5]. Out-of-domain sources such as Wikipedia or newer general language models like BERT [6] have not been extensively explored for this task on medical text.

Exploring use of non-sensitive data, the validity of using pseudonymised clinical text for de-identification is studied in [7] where the Stockholm EPR PHI Pseudo Corpus [8] is used and compared with Stockholm EPR PHI Corpus, the non-pseudonymised corpora. It is shown that the results using pseudonymised corpora as training data are slightly decreased, suggesting limited potential.

In another approach, McMurray et al. [3] used both EHR text and text from publicly published medical journals for training purposes. The authors argued medical publications will generally not contain enough protected health information (PHI) information, and this could be a discriminating factor. In contrast, a recent study by Berg et al. [9] found no additional benefits of using out-of-domain training material for de-identification using deep learning approaches.

Whether non-sensitive medical text such as scientific medical publications or even text from the general domain is useful for de-identification, is still a matter without fully resolved clarity. In this study we test both these non-sensitive sources and contribute evidence to help answer the question.

2. Method

Experiments will compare the effect of adding medical scientific text versus text from the general domain to the training set for a de-identification deep learning model. The comparisons are with (i) the base embedding layer from the EHR text, (ii) EHR text plus medical scientific text, and (iii) EHR text plus Wikipedia word vectors. These data sources are detailed in the succeeding subsections.

2.1. Stockholm EPR PHI Psuedo Corpus

Stockholm EPR PHI Pseudo Corpus² is a Swedish EHR corpus, which has been de-identified and pseudonymized [8], and where the tokens are annotated with PHI information. Stockholm EPR PHI Psuedo Corpus is part of the Health Bank [10], the Swedish Health Record Research Bank³. The Health Bank encompasses structured and unstructured patient records data from 512 clinical units from Karolinska University Hospital collected from the years 2007 to 2014 encompassing over 2 million patients. The dataset uses a less fine-grained annotation scheme (IOB), indicating [I=inside token], [B=begin token], and [O = not PHI token].

²Research approved by the Regional Ethical Review Board in Stockholm; permission no. 2014/1607-32.

³Health Bank, <http://www.dsv.su.se/healthbank>

2.2. Scientific medical journal and Swedish Wiki word vectors

Scientific medical text is based on the Läkartidningen corpus (The Swedish scientific medical journal from 1996 to 2005). Läkartidningen has publicly available articles at Språkbanken⁴. Wiki word vectors are pre-trained word vectors created with fastText from Swedish Wikipedia text [11], and are publicly available at fastText⁵. They are designed with no specific downstream task in mind, but what makes them interesting is their use of character-level n-grams, where a single word can be represented by several character n-grams.

2.3. Deep recurrent neural networks

A state of the art deep learning algorithm previously used on health data [5], the Bidirectional Long Short-Term Memory algorithm with conditional random fields (BI-LSTM-CRF), was used in the experiments, as implemented in TensorFlow/Keras⁶. For the scientific medical text, we used another state of the art method, Word2Vec, to create the word embeddings. Wikipedia word vectors are made available to the public pre-trained and ready for downstream tasks. Both sources have 300 dimensional vector representation.

3. Results

The results in Table 1 show a clear improvement in results, from adding Wiki word vectors to the base embedding layer with EHR data only. We also observe that adding scientific medical text improves performance, but falls short of Wiki word vectors.

PHI	EHR			EHR + Scientific medical text			EHR + Wikipedia		
	P %	R %	F1	P %	R %	F1	P %	R %	F1
Age	66.67	40.00	50.00	100.00	80.00	88.89	100.00	80.00	88.89

Table 1. De-identification results based on the three comparisons, P=Precision, R= recall, both percentage

There are a number of reasons that could explain why the Wikipedia text performed better than medical text. First, Wikipedia is a rich source of information which contains both general text and medicine-related text as well. In addition, a number of PHI information such as first and last names, ages, year, and location are present in the text. Also, the scientific medical journal corpus in Swedish (Läkartidningen) produced 118,683 vectors while Wikipedia, on the other hand, produced 1,143,274 vectors.

Further, we observed that the scientific medical text start's out with a relatively high error loss in each epoch, while initial error loss is much lower for Wikipedia. In terms of

⁴Läkartidningen, <https://spraakbanken.gu.se/swe/resurs/lakartidn-vof>
⁵fastText, <https://fasttext.cc>
⁶TensorFlow, <http://www.tensorflow.org>

the improvement in F1 measures (see Figure 1), there was significant performance gain for *Age* and *Phone Number*. For scientific medical text, we noted poorer performance for some PHI information like first names and last names, compared to the EHR baseline.

Figure 1. The graph shows the PHI differences in F1 measures between scientific medical text and the EHR baseline (MED-EHR) and between Wikipedia and the EHR baseline (WIKI-EHR) respectively.

4. Discussion

It appears the general consensus in scholarship is that training on general-domain text is not appropriate for tasks on clinical text, since clinical text is so different that it represents a unique linguistic genre. The language in clinical notes is meant for other healthcare professionals. Clinicians and nurses write these notes under time pressure, therefore the text has abbreviations, misspellings, unusual grammatical constructs and other errors and ambiguities.

Our results support a counter-argument that PHI information is distinct from clinical text since PHI information is general, as opposed to clinical procedures, medication or medical concepts that are present in clinical text. Therefore, it could be appropriate to use non-sensitive text in the general domain as training data for detecting PHI information. Also, deep learning architectures have been reported to show good performance under different domains and languages.

The poor results obtained with scientific medical text is consistent with previous assertions made in the literature, that is, scientific text is not likely to contain names and surnames in meaningful contexts [3]. However, the significant improvement in *Age* and *Phone Number* suggest that scientific medical text could still be useful for detecting specific PHI information. Therefore, combining this medical text with other sources could be a viable option.

5. Conclusion

Current results suggest that non-sensitive resources in the general domain can be useful for de-identification tasks on clinical notes. Even though deep learning models are generally thought of as data-hungry, current results raise the prospect of creating robust models; where the primary training data is sensitive and low resourced. In the future, we will test non-sensitive resources and language models to adapt and transfer deep learning models for de-identifying clinical notes between closely similar Nordic languages; such as between Swedish and Norwegian clinical notes.

Abstract: We conducted a study to evaluate the algorithms based on deep learning to automatically diagnosis of GON from digital fundus images. A systematic articles search was conducted in PubMed, EMBASE, Google Scholar for the study that investigated the performance of deep learning algorithms for the detection of GON. A total of eight studies were included in this study, of which 5 studies were used to conduct our meta-analysis. The pooled AUROC for detecting GON was 0.98. However, the sensitivity and specificity of deep learning to detect GON were 0.90 (95% CI: 0.90-0.91), and 0.94 (95%CI: 0.93-0.94), respectively.

Keywords: Glaucoma, glaucomatous optic neuropathy, deep learning, artificial intelligence, fundus image.

1. Introduction

Glaucoma has already been emerged as one of primary cause of blindness, affecting approximately 66.8 million people worldwide [1]. It is often considered as a progressiveness neurodegenerative, multifactorial disease, characterized by the continuous loss of ganglion cells (RGCs) and damage of optic nerve atrophy and the visual cortex [2]. Most cases of GON are asymptomatic until to be reached in late stage. Since the diagnosis of GON is very subjective and qualitative, and early detection of GON can help to improve treatment plan, monitoring of the quality of life and to prevent visual impairment. Screening of GON is always achieved by manually assessing optic nerve structure in the digital fundus image. However, this process is labor-intensive, time-consuming and the performance of GON detection solely depend on the skill and experience of ophthalmologists [3]. A fully automated system would enhance the quality of existing care by providing diagnostic support to ophthalmologists and

¹ Yu-Chuan (Jack) Li, MD, PhD Graduate Institute of Biomedical Informatics, Taipei Medical University, Taipei, Taiwan. Email: jack@tmu.edu.tw / jaak88@gmail.com

could contribute to the accessibility of patients care by generating large-scale automated screening systems [4].

Deep learning algorithm has already appeared as a cutting-edge solution for successful detection of diabetic retinopathy [5], glioma [6], macular degeneration [7]. An automated system could also play an important role in the diagnosis of GON early that could improve patients care. It would contribute to strengthening the treatment adherence and by providing the importance of GON medications and surgeries. Here, we conducted a systematic review with meta-analysis to evaluate the performance of deep learning for detecting GON using digital fundus images. It can help to establish evidence of the ability of deep learning model for detecting GON.

2. Methods

This study followed the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) that is based on Cochrane's Handbook for Systematic Reviews [8].

Databases Search A systematic search was conducted in PubMed, EMBASE, Scopus, Google Scholar for relevant studies between 2010 and 2019. Some control keywords: "deep learning", "Convolutional neural network", "CNN", "DL", "glaucoma", "glaucomatous optic neuropathy", "GON" were used as a search term. To ensure comprehensiveness, the reference lists of retrieved articles were checked carefully to get additional relevant studies.

Eligibility Criteria Eligibility was restricted to studies that evaluated the performance of deep learning algorithms to detect glaucoma. Studies were excluded if they were not published in English, and published as review, short report, editorial, letter to editors.

Selection Process Two authors (MMI, TNP) independently screen the titles and abstracts of all retrieved relevant studies. They selected studies based on the pre-specified selection criteria. Any disagreement between them during the screening process was resolved by the main investigator (YCL).

Data Extraction Data collection forms were used to extract the required information from included studies retrieved initially. Two authors first removed duplication by checking author name, publication date, sample size. Afterwards, they collected author name, publication year, total sample size, number of images, methods, external validation information, the performance of deep learning, sensitivity, specificity, true positive, true negative, false positive and false negative.

Assessment of Risk Bias Same two authors independently used QUADAS-2 for assessing the individual quality of each study. The QUADAS-2 tool is recommended for evaluating the risk of bias and applicability of primary diagnostic accuracy studies. QUADAS-2 tool consists of four areas such as patient selection, index test, reference standard and flow and timing.

Statistical Analysis The meta-analysis was performed on qualifying studies that reported the performance of deep learning for detecting GON with sensitivity and specificity, and a total number of images. We then calculated the true positive, false positive, true negative and false negative to generate area under the receiver operating characteristic curve. A random-effect model was used to generate the

pooled sensitivity, specificity, positive- and negative likelihood ratio and diagnostic odds ratio. All the analyses were performed using Meta-Disc (V-1.4) software.

3. Results

The literature searches of the electronic databases yielded 150 articles. After screening of the titles and abstracts, 137 studies were excluded due to lack of inclusion criteria. 13 articles went for full-text review; a total of 8 articles were then selected for our study [3, 9-15]. 5 out of 8 studies were included in the meta-analysis. Publication years ranged from 2018-2019. Three studies were from China, 2 from Japan, 1 from India, 1 from South Korea and 1 from the United States. All the studies were used the CNN model to detect GON from digital fundus images. The QUADAS-2 tool assessment showed that 5 studies had moderate applicability, and the concerns about the applicability of the remaining studies were considered as low.

Table 1: Characteristics of included studies.

Author	Country	Method	Total Image	Data source
Liu 2019	China	CNN	274,413	CGSA*
Asaoka-2019	Japan	CNN	1,364	MRCH
Shibata-2018	Japan	CNN	1,364	MRCH

Note= CGSA: Chinese Glaucoma Study Alliance *other dataset also used. MRCH: Matsue Red Cross Hospital, KMC= Kasturba Medical College, Kim's Eye Hospital, The African Descent and Glaucoma Evaluation Study and the University of California, San Diego (UCSD), NR= Not reported.

Five studies evaluated the performance of deep learning model for accurate detection of GON. The deep learning model showed the higher performance to accurately detect GON. The overall pooled AUROC for deep learning algorithms to detect GON was 0.98 (**Figure 1**). The sensitivity and specificity were 0.90 (95% CI: 0.90-0.91), and 0.94 (95%CI: 0.93-0.94), respectively.

Furthermore, the pooled positive likelihood ratio and negative likelihood ratio were 16.77 (95%CI: 6.42-43.79), and 0.06 (95%CI: 0.02-0.15). The heterogeneity among the studies was $I^2=99.8\%$ and $I^2= 99.4\%$, respectively. Moreover, the diagnostic odds ratio was 292.53 (50.13-1706.94).

4. Discussion

In this study, we evaluated the performance of deep learning algorithms for detecting GON from the digital fundus images. Our findings suggest that deep learning model has immense potential to detect GON with high sensitivity and specificity in a diverse population. The diagnosis accuracy, sensitivity and specificity of traditional computer

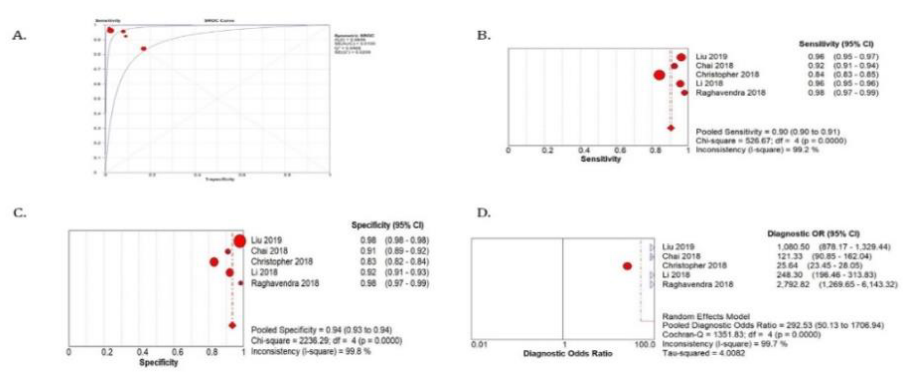

Figure 1: Classification performance of deep learning model. a) Receiver operating characteristic curve b) sensitivity c) specificity d) diagnostic odds ratio

vision methods are close to 60% [16], whereas the pooled AUROC, sensitivity, and specificity of deep learning model are 0.98, 0.90, and 0.94, respectively. The performance of the deep learning model can help to make an automatic screening tool to detect GON early for better patient's care. Improved sensitivity and specificity of tests increase the feasibility of GON screening programs by reducing the burden of false-positive [12]. Early diagnosis of GON using automated tools could have a crucial role in supporting ophthalmologist, as patients with glaucoma are unaware of their condition until central visual acuity is damaged. An automated technique would help to improve performance, reduce the healthcare cost, and give the same performance in different digital images.

There are several advantages of using deep learning for the detection of GON from digital fundus images. First, no need to do conventional steps such as feature extraction, dimensionality reduction and feature ranking [17]. Second, it does not require data preprocessing which usually influence in traditional machine learning techniques. However, there are several challenges to use deep learning techniques in GON diagnosis. First, it takes a higher number of GON images to train the model for getting the optimum performance. Second, generalizability problem, it means the model would perform the same in different databases.

5. Conclusion

Findings of our current study showed that deep learning model has immense potential to detect GON (high sensitivity and specificity). Implementation of deep learning-based automated tools could be cost-effective and improve the accessibility of GON screening in a remote setting. Having ensured the generalization of automated diagnosis of GON, a dataset with different ethnicities could be tested.

Abstract. The MIRACUM consortium is developing a Clinical Trials Recruitment Support System to support the data-driven recruitment of patients for clinical trials. The design of the prototype includes both open source solutions (OMOP CDM, Atlas) and open standards for interoperability (FHIR). The aim of the prototype is to create a patient screening list of potential participants for a clinical study. The paper shows the modular structure and functionality of the prototype building the foundation for the practical implementation of the CTRSS and, at the same time, demonstrating the use of open source solutions and standards for the development of clinical support systems.

Keywords. clinical trial recruitment support system, FHIR, OMOP, OHDSI, secondary use of electronic health records, automation, open standards, decision support systems

1. Introduction

Clinical trials are fundamental in clinical research and in evidence based medicine since they are needed to evaluate new treatment methods, the effectivity of drugs, or new diagnostic tools [1]. However, many studies fail during the recruitment phase for the following two reasons: either the minimum necessary number of patients is not reached or the recruitment process takes too much time and effort to find enough eligible patients to participate [2] [3]. One option to overcome those issues is the specific reuse of already observed data during inpatient treatment. Since the availability of digital health care data is growing rapidly it offers high potential for reuse in clinical research [4]. The idea of automated screening electronic health care data is not new. During the last ten years the number of publications on clinical trial recruitment support systems (CTRSS)

¹Corresponding Author: Ines Reinecke, Teamleader Research Infrastructure, Research Associate, Fetscherstrasse 74, 01307 Dresden, Germany; E-mail: ines.reinecke@uniklinikum-dresden.de

is continuously increasing. This trend demonstrates the importance and need of such systems to allow faster and more efficient patient screening [5]. Köpcke et al. [5] pointed out the lack of standards and missing interoperability of CTRSS as well as a missing formalisation of eligibility criteria for the definition of a potential trial cohort. Thus a major goal of the MIRACUM consortium [6] is to provide a modular CTRSS based on open standards. This approach shall ensure interoperability and flexibility to connect to other systems such as study registries and hospital information systems. As one of four consortia MIRACUM is part of the German Medical Informatics Initiative (MII). The MII brings together 30 university hospitals and a number of industry partners to establish data integration centres. The aim is to provide clinical health care data from various source systems in one place to ensure to "prove their benefit for researchers, doctors and patients" [7]. To demonstrate the benefits of integrated data one use case the MIRACUM consortium is responsible for is "Alerting in care - IT support for patient recruitment". This paper illustrates how to build a CTRSS concept that consists of separate modules, can be transferred to other locations, make use of existing open source tools and benefit from open standards.

2. Methods

To address the topics modularity, transferability, open source tools and open standards, a heterogeneous group of computer scientists, medical information scientists, data scientists and physicians joined forces to develop the CTRSS prototype. The team evaluated how the communication between loose coupled modules of the prototype can be done based on Representational State Transfer (REST) over HTTP protocol and what is needed to represent data using the Fast Healthcare Interoperability Resources (FHIR) developed by Health Level Seven Organization (HL7) standard for data exchange. A common data model was needed to store data that gets searched for potential trial participants by the CTRSS prototype. The *Observational Health Data Sciences and Informatics* (OHDSI) organization consists of a rapidly growing worldwide community of universities to foster worldwide medical scientific community and to improve scientific research [8]. Thus they developed a common data model (CDM) *Observational Medical Outcomes Partnership* (OMOP) including a set of standardized vocabularies (e.g. SNOMED, LOINC, rxNorm, ICD10) and their translations between each other to allow researchers to speak a common language when exchanging data. To validate OMOP CDM is a proper patient data storage needed by a CTRSS we installed it on a PostgreSQL database and added standardised vocabularies using the OHDSI Athena web application. Athena is a service that provides regular updates of the vocabularies to ensure utilization of the most recent vocabulary versions. In Germany a modified version of the ICD10 world health organization (WHO) vocabulary is in place to serve local billing purposes. Thus the ICD10GM vocabulary has been added as an additional vocabulary to the OMOP database based on the work done by Maier et al. [9]. In a next step the patient data based on the MII core data set were imported into OMOP. All data included in the MII core data have been mapped into the OMOP CDM successfully. Afterwards the Atlas web application was used to define cohorts based on the eligibility criteria of a clinical trial using a web interface for several clinical trials. The exchange of cohort definitions between different locations was done with the import and export capability of the Atlas

web application. All information of defined cohorts was stored in the OMOP database. Furthermore OHDSI provides a Web Application Programming Interface (API) based on REST for the OMOP CDM. The REST Web API was used to realize the access to already defined cohorts. This included the execution of cohort definitions against the OMOP database, status checks of a cohort execution and the call of a result list of patient ids for a certain cohort definition. To implement the notification of research teams about any changes on the patient screening lists, we evaluated the functionality offered by the FHIR HL7 standard. FHIR provides subscription resources that allows us to register a certain resource to act on any event such as change, create or delete. The subscription resource was configured to use a certain communication channel such as e-mail, REST post request and others.

3. Results

The CTRSS prototype consists of separate modules based on an architecture proposed by Trinczek et. al. [10]. Each module targets a small set of similar features and is implemented as a REST based micro-service with well-defined service boundaries. All module interfaces have a properly documented API. As shown in Figure 1 the prototype CTRSS is composed of the following five modules:

- patient data module
- Atlas web application
- query module
- notification module
- screening list module

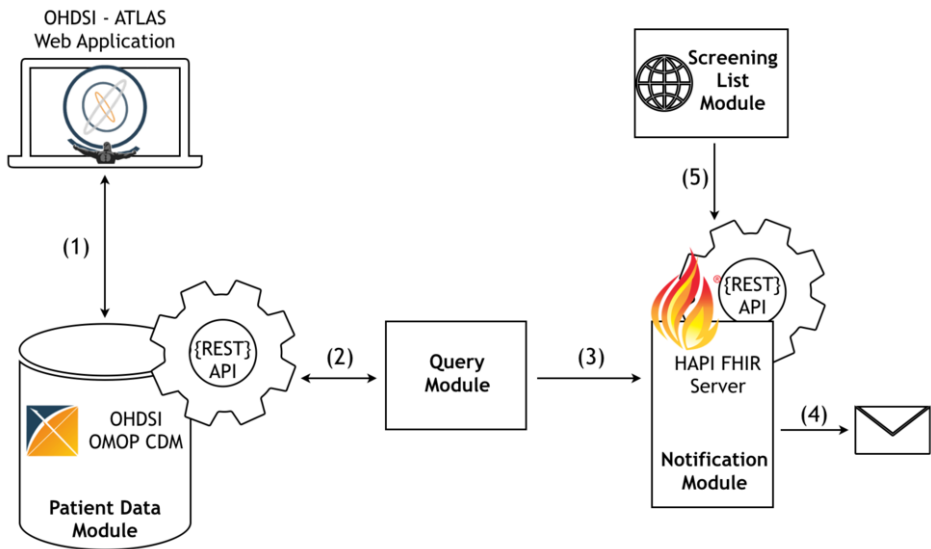

Figure 1. Architecture of the CTRSS

The process of creating a patient screening list consists of the following five main steps:

1. cohort definition using the ATLAS web application
2. generation of a cohort and retrieval of its contents from the OMOP database done by the query module
3. generation or update of the screening list with retrieved patients as a FHIR list-resource done by the query module
4. notification based on any event on a FHIR list-resource done by the notification module
5. screening list module receives new or changed screening lists

The patient data module is based on the OMOP CDM (version 5) and it stores all observational data of a patient. In the first step the Atlas web application is being used for cohort definition. On successful cohort definition an unique identifier of the defined cohort is returned. All cohort definitions built with Atlas can be exported to other locations. The query module is a custom implementation using REST calls to send and retrieve data. In step two the query module generates the patient list using the cohort identifier that is handed over after cohort definition with Atlas. Based on a defined scheduling or on notification when patient data changes, the query module runs a REST POST query against the OMOP Web API to generate the list of potential trial participants in the database. The query module uses another REST call to check the current status of a cohort generation. After successful cohort creation the query module retrieves the patient list. In step three the list of patients for a particular trial is sent using a FHIR list-resource that contains all patient ids. There has been a subscription resource created for the list-resource that sends e-mail messages to recipients when a list of patient ids gets created or changed on the FHIR server. The patient screening list module is a custom web application that reads the list-resources data from the FHIR server. It displays all potential patients for a trial of interest based on the cohort id. The screening list module is implemented as a web application based on HTML 5 and the java script framework Vue.js.

4. Discussion

The CTRSS prototype is based on separate modules that consist of a strong encapsulation to hide the details of the implementation that ensure a loose coupling between each other and thus addresses the lack of missing interoperability [11]. Our approach provides great advantages in terms of technology heterogeneity, resilience, scalability, deployment efficiency, composability, and optimization for replacement as stated by Sam Newman [12]. Hence compared to monolithic software, the modular CTRSS prototype introduced by us allows to accelerate development cycles, reduce deployment efforts, and provide improved scalability. Development teams can exchange single modules without affecting others as long as the interfaces are the same and thus flexibility of the whole system increases. Additionally the scaling of each module can be done based on performance requirements individually instead of scaling the whole prototype. As stated by Köpcke et. al. [5] "many CTRSS are designed to fit the existing infrastructure of a clinical care provider or the particularities of a trial" and therefore most existing CTRSS are limited to local environments and conditions that cannot be transferred to other locations nor adapted to trials with different characteristics. Our CTRSS prototype was built to over-

come those limitations as it is a transferable solution that can be used across different locations. Additionally the usage of FHIR for the exchange of electronic healthcare data using web technologies enables the prototype to be extended and connected to many other health care systems. In the future the prototype can be extended to send back notification on new potential trial participants to existing health information systems (HIS). With the OMOP CDM the used patient data is transformed into a standardized format that allows scientists to search for potential participants at multiple locations national wide and with the option for extension to an international level in future projects. The usage of OHDSI Atlas allows scientists to share defined cohorts with others. This extends the range of coverage when searching for potential participants and thus increases the chance to meet set expectations in terms of number of participants. Our prototype is currently limited in terms of usage and result reporting. Therefore no results on the success of patient recruitment can be provided. The exchange of data between different locations has to be done in a next step. The test and deployment of the prototype within the MIRACUM consortium including reporting of the results and outcomes needs to be addressed in follow-up publication as suggested by Köpcke et. al. [5].

Abstract. Identifying adverse events in clinical documents is demanded in retrospective clinical research and prospective monitoring of treatment safety and cost-effectiveness. We proposed and evaluated a few methods of semi-automated muscle weakness detection in preoperative clinical notes for a larger project on predicting paresis by images. The combination of semi-expert and machine learning methods demonstrated maximized sensitivity = 0.860 and specificity = 0.919, and largest AUC = 0.943 with a 95% CI [0.874; 0.991], outperforming each method used individually. Our approaches are expected to be effective for autoshaping a well-verified training dataset for supervised machine learning.

Keywords. Electronic Health Records, Neurosurgery, Natural Language Processing, Adverse Events, Logistic Regression, ROC-analysis

1. Introduction

Identifying adverse events in clinical documents is highly demanded in retrospective clinical research and monitoring of treatment safety and cost-effectiveness [1]. However, these entities are described using free text in medical records. To extract information on complications following neurosurgery, the examination of narrative medical texts is likely needed. These activities are time-consuming for experts and almost impractical when dealing with big data collected through decades. Despite the effective machine learning implications in natural language processing, the absence of formalized ground truth variables in unstructured data makes the use of supervised techniques challenging. Thus, the text annotation would benefit from effective automation. Recently, our group proposed an information extraction algorithm (IEA) for detecting adverse events in neurosurgery using documents written in a natural rich-in-morphology language [2]. This study aimed to test our IEA in the identification of preoperative extremity muscle weakness in patients with glial tumors and to compare its feasibility with supervised machine learning.

¹ Corresponding author, E-mail: glebda@yandex.ru.

2. Methods

The task of any extremity weakness (paresis) detection in medical texts originated from the project on muscle strength prediction by deep learning on medical images (supported by Russian Foundation for Basic Research (RFBR) grant 19-29-01154). The technical problem we tried to solve was a classification of patients as having paresis or not. The relevant data were obtained for a cohort of 429 patients with accessible magnetic resonance images (average age 39.8 ± 17.9 y.o., 194 (45.2%) males) who underwent glial tumor resection at N.N. Burdenko National Medical Research Center of Neurosurgery in a period between 2009 and 2018. In this sample, the narrative description of the preoperative neurological status in the Russian language was supplemented with the quantitative (0 to 5 scores) estimation of muscle strength for each extremity, which allowed us to create a ground truth binary variable (0 – no paresis, 1 - any paresis) [3]. That dataset was used in testing of our algorithm's performance and comparing it to supervised machine learning. All the data extracted from electronic health records (EHR) were processed and analyzed within the R programming environment (version 3.5.0) in RStudio IDE for MacOS (version 1.1.453) using *rsample*, *drlib*, *broom*, *yardstick*, *glmnet*, *doMC*, *dplyr*, *tidyr*, *stringr*, *tidytext*, *tidyverse*, *quanteda*, *qdapRegex*, *tm*, *scales*, and *cutpointr* packages.

2.1. Event detection in EHR

Source text documents related to neurological examination upon admission were selected to build the initial corpus of 429 medical cases, which was preprocessed as follows:

- words transformed to lower case;
- all the characters and symbols except for letters and single spaces removed;
- texts tokenized with a space separator;
- stop-words and meaningless words (single letters, artifacts, etc.) removed;
- spelling corrected and tokens lemmatized.

The unique lemmas were screened by an expert to select those likely related to or certainly used in the paresis description. The selected lemmas shaped the “paresis lexicon” list. The context of each selected term was defined from *n*-grams containing it. Considering the importance of prepositions in the Russian language, we have seen 5-grams sufficiently interpretable. Those 5-grams were rated by 0.5 (if indicating any paresis with uncertainty), 1 (if indicating any paresis obviously), or 0 (if no paresis was mentioned) by the expert. We tested two modes of using the scores to decide whether muscle weakness is present in the source documents containing the rated 5-grams. The first option considered paresis in only those medical records in which at least one 5-gram received 1 point (IEA1, “utmost confident algorithm”). In the second mode, the presence of paresis was decided considering the sum of scores for all rated 5-grams found in each case history based on an optimal cutpoint (IEA2, “highly suspicious algorithm”).

2.2. Logistic regression with LASSO regularization

The subset of 429 clinical records containing a narrative and digital preoperative assessment of muscle strength was used to build a supervised logistic regression model

(LR1) on a “bag of words” text representations (sparse vectors). The target binary variable indicated the presence/absence of paresis. The model was evaluated with 5-fold validation (within training data consisted of 75% of the initial sample) and LASSO regularization, 300 times repeatedly using resampling. We rebuilt the LR1 model with the same technique adding more textual data referring to preoperative neurological status, however, written postoperatively (LR2). Finally, IEA1 was used in combination with LR2 to find whether it improves the prediction (IEA1+LR2). In the latter approach, all the cases of paresis confidently identified by IEA1 were automatically accepted, and LR2 predicted the rest.

2.3. Performance evaluation

The quality of the IEA, the logistic regression models, and their combination was evaluated using ROC-analysis. The sensitivity (SENS, also referred to as recall), specificity (SPEC), accuracy (ACC), positive predictive value (PPV, also referred to as precision), negative predicted value (NPV), F-measure (F), cutoff value (COV) and area under ROC-curve (AUC) were computed for all methods on test sets in each iteration of resampling. The bounds of 95% AUC confidence interval were calculated at each iteration using bootstrapping techniques. The cutoff point was chosen on the training sets to maximize the sum of sensitivity and specificity for every method. All the metrics were averaged across 300 iterations.

3. Results

3.1. Evaluation of the paresis detection algorithms

We selected 122 terms to shape “paresis lexicon” out of unique 854 lemmas for 1199 original tokens from 429 cases. These 122 concepts were represented in 491 5-grams screened by the expert. The paresis was suspected with uncertainty by 72 and more confidently by 92 n-grams. The IEA1 showed the best accuracy, positive predictive value, and specificity operating with an only binary (0 or 1) output (Table 1). The output of IEA2 ranged from 0 to 8.5. However, the cutoff point maximizing the sum of sensitivity and specificity treated all cases of 0.5 scores and above as paresis (Table 1). AUC for both cases was estimated above 0.8 on average, with IEA2 outperforming IEA1 (Table 1, Figure 1, A).

Table 1. The quality metrics of information extraction algorithms, logistic regression models and combined approach.

Method	COV*	SENS	SPEC	ACC	PPV	NPV	F	ROC AUC [95% CI]
IEA1	1	0.633	1	0.907	1	0.889	0.775	0.817 [0.771; 0.863]
IEA2	0.5	0.789	0.897	0.869	0.723	0.926	0.754	0.875 [0.833; 0.914]
LR1	0.267	0.668	0.906	0.846	0.723	0.892	0.673	0.860 [0.757; 0.945]
LR2	0.272	0.762	0.925	0.877	0.815	0.904	0.777	0.911 [0.831; 0.972]
LR2 + IEA1	0.268	0.860	0.919	0.902	0.821	0.942	0.837	0.943 [0.874; 0.991]

* for all algorithms, ‘paresis’ cases were considered when output \geq cutoff point.

3.2. Evaluation of logistic regression and combined approach

The LR1 and LR2 algorithms showed better performance than semi-automated expert dependent IEA1 and IEA2, with LR2 superior to LR1 (Table 1, Figure 1, B and C respectively). Regularization led to the selection of words most significant for paresis detection. However, the combination of IEA1 and LR2 simultaneously resulted in the largest AUC in our tests (Table 1, Figure 1, D).

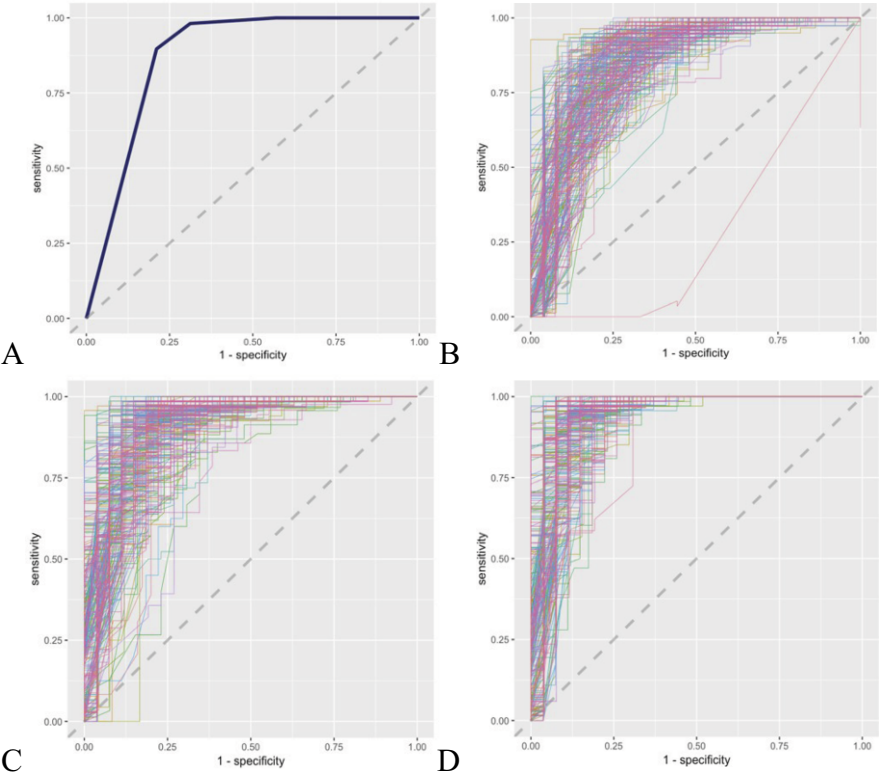

Figure 1. ROC curves superimposed after 300 times of resampling. A – model IEA2, B – model LR1, C – model LR2, D – model IEA1+LR2. The improvement of performance is observed from A to D.

4. Discussion

Natural language processing with machine learning machine learning has occasionally been applied in neurosurgical adverse events detection. J. Gaebel et al. (2015) suggested using semantic preprocessing for adverse events extraction in neurosurgery [4]. B. Campillo-Gimenez et al. (2013) identified surgical site infections with the NOMINDEX tool and text similarity in vector space [5]. N. Tvardik et al. (2018) detected healthcare-associated infections in clinical notes [6]. However, the idea of adverse events extraction from texts is challenged in other medical domains (e.g., infections or drug trials) and with other technologies (e.g., word embeddings, neural networks, etc.) [1], [7].

In our study, the IEA1 method appeared to be robust in the detection of paresis

with 100% specificity and positive predictive value (which still needs verification on a larger dataset). Despite the moderate sensitivity, this semi-expert method might be required in retrospective research when a sufficient number of ‘paresis’ cases should be obtained for clinical study, and no quantified muscle strength assessment is provided for supervised machine learning. However, collecting more data available for IEA1 and a combination of it with logistic regression provides a more flexible instrument to enroll true positive cases and true negative cases in the main and control study groups with stronger confidence at a large number. The other implication of these methods is in prospective adverse events monitoring. IEA1+LR2 favoring maximal sensitivity might be preferable. In general, we consider this methodology feasible for other adverse events detection. IEA1 and IEA2 may be especially efficient in detecting rare cases.

The most important limitation of this work is a relatively small dataset. All methods described above will be further tested on a significantly larger data volume. It would also be valuable to estimate all the models on the dataset with no quantitative muscle strength assessment. The more resource-intensive expert verification will be required in future studies.

5. Conclusion

The method for paresis detection in unstructured medical records showed its efficiency, however testing on a larger dataset is required. The event detection algorithms based on the combination of expertise and machine learning outperformed each approach used independently.

This project was supported by the RFBR grant 18-29-22085. The extraction of data for glial tumors was also supported by the RFBR grant 18-29-01052.

Abstract. The disease multiple sclerosis (MS) is characterized by various neurological symptoms. This paper deals with a novel tool to assess cognitive dysfunction. The Brief Visuospatial Memory Test-Revised (BVM-T-R) is a recognized method to measure optical recognition deficits and their progression. Typically, the test is carried out on paper. We present a way to make this process more efficient, without losing quality by having the patients using a tablet App and having the drawings rated with the use of a machine learning (ML) algorithm. A dataset of 1'525 drawings were digitalized and then randomly split in a training dataset and in a test dataset. In addition to the training dataset the already trained drawings from a preliminary paper were added to the training dataset. The ratings done by two neuropsychologists matched for 81% of the test dataset. The ratings done automatically with the ML algorithm matched 72% with the ones of the first neuropsychologist and 79% of the ones of the second neuropsychologist. For a semi-automated rating we defined a threshold value for the reliability of the rating of 78.8%, under which the drawing is routed for manual rating. With this threshold value the ML algorithm matched 80.3% and 86.6% of the ratings of the first and second neuropsychologists. The neuropsychologists have in that case to manually check 17.4% of the drawings. With our results it is possible to execute the BVM-T-R Test in a digital way. We found out, that our ML algorithms have with the semi-automated method the similar matching as the two professional raters.

Keywords. BICAMS; BVM-T-R; Convolutional neural network; Machine Learning, Multiple Sclerosis, digitalize

1. Introduction

The disease multiple sclerosis (MS) is characterized by various neurological symptoms, including motor weakness and spasticity, coordination problems, fatigue, sensory, bladder and cognitive dysfunction [1]. This paper deals with a novel tool to assess cognitive dysfunction. The Brief Visuospatial Memory Test-Revised (BVM-T-R) [2], which is part of the Brief International Cognitive Assessment for MS Test Battery

¹ Bern University of Applied Sciences Engineering and Information Technology, Höhweg 80, CH-2502 Biel / Bienne, E-mail: m.birchmeier@hotmail.com

(BICAMS) is a validated instrument to assess cognition in MS patients [3]. Currently, the BVMT-R is carried out on paper in the presence of a neuropsychologist. Briefly, the patient is presented a page with six geometric figures for ten seconds to memorize them. Then he tries to redraw them from memory considering the correctness and position of each figure. These drawings are then evaluated by a neuropsychologist. A figure, which is both correct in details and position on the paper receives a rating of 2 points. If the drawing is not correct but similar to the original or correct but in the wrong position, the rating is 1. If the drawing is wrong the rating is 0 points. This is a time-consuming procedure for both players.

In this paper, we present a way to make this process more efficient, without losing quality by having the patients using a tablet App to look at, memorize and draw the figures and having the drawings rated automatically or semi-automatically with the use of a machine learning (ML) algorithm. We have therefore defined the following research question: “Can the drawings of the BVMT-R be rated by a Convolutional Neural Network (CNN) with the same accuracy as a neuropsychologist?”.

2. Method

First of all, a mobile app was developed to digitalize the 294 (page of six drawing of geometric figures) paper-based patient data, which were provided by the COGITO GmbH in Düsseldorf and evaluated by their neuropsychologist (N1). Those patient data contain only the form A (see Table 1 below) of the BVMT-R. After eliminating 239 empty drawings, from the total of 294 patient’s data at 6 drawings per page, a total of 1’525 drawings remained and were included in this patient dataset.

This dataset was then randomly split in 1’220 drawings (=80%) for the training dataset and 305 (=20%) for the test dataset. In addition to the training dataset the already trained drawings from the preliminary paper [4] were added, which resulted in a total training dataset of 1’790 drawings (see table 1).

Table 1. Number of training data (m) and test data (n) per figure.

Number	Figure	Data
1		m = 352, n = 57
2		m = 309, n = 52
3		m = 320, n = 54
4		m = 267, n = 47
5		m = 281, n = 48
6		m = 261, n = 47
Total		m = 1’790, n = 305

For the ML algorithm a CNN was chosen, because this algorithm has been developed for visual object classifications [5]. The CNN gives as an output a rating of the image with a probability value of the reliability of the rating [6].

Furthermore, the test dataset was reevaluated by a second neuropsychologist (N2) from the University Hospital Zurich, to compare the evaluation between two neuropsychologists from different centers. The evaluation of the neuropsychologist from the University Hospital Zurich is also used as external validation unit.

Since the manual rating procedure of a single neuropsychologist is not representing a clear gold standard for the ML algorithm, its rating results cannot rely on the ratings of a single neuropsychologist. Therefore, in order to answer the research question, we use the result of the comparisons between the ML algorithm and the two individual neuropsychologists and consider these results with the comparison between both neuropsychologists among themselves.

Various statistical methods were used to evaluate the ML algorithm: Sensitivity, specificity, the positive and negative prediction value [7], the significance test [8] and the Cohen's kappa test to evaluate the interrater reliability of assessments between the neuropsychologists themselves and the ML algorithm [9].

In a second step, a semi-automated rating methodology was used, keeping the rating of the ML algorithm when the rating reliability was above a defined threshold value and otherwise redirecting the drawing to the neuropsychologist for manual rating.

3. Results

The two neuropsychologists (N1 and N2) rated the test data and they were compared with each other. Their rating was identical for 81% of the drawings. Cohen's Kappa (K) was 0.62.

We can see that our neuropsychologists have an equal match with a Kappa of 0.62 like the scientists of Brazilian study [10].

The agreement between N1 and ML is by 72% ($K = 0.45$) and between N2 and ML 79% ($K = 0.56$).

With the second method (semi-automated rating) in order to set the threshold value, a ROC curve was generated per label and comparison from the sensitivity and the specificity.

Figure 1. ROC curve per label from the comparison between N1 and ML.

Figure 2. ROC curve per label from the comparison between N2 and ML.

The area below the ROC curve is a measure of the quality of the evaluation per label [11]. This means that if the ML algorithm cannot detect labels, the ROC curve forms a diagonal (50% area below the ROC curve). The better the ML algorithm, the larger the area below the ROC curve. The area below the ROC curve can also be seen as the probability that a label will actually be evaluated from the ML as the label from the neuropsychologist.

Table 2. Area below the ROC curve.

	N1 <-> ML	N2 <-> ML
Label 0	71.5%	75.6%
Label 1	72.0%	81.3%
Label 2	82.6%	89.7%
Average	75.4%	82.2%
Average total	78.8%	

This threshold value was used again to calculate the agreement in percent and in kappa. In addition, the number of drawings that must be checked manually for each threshold value was specified. This shows how the agreement changes and how many drawings have to be checked manually by a neuropsychologist.

With the threshold, the N1 and ML has an agreement of 80.3% (Kappa = 0.62) and the agreement between N2 and ML was 86.6% (Kappa = 0.73). N1 and N2 have to manually check 53 drawings (of the 305).

The significance test is intended to show how many ratings of the ML algorithm do not match with the ratings of N1 and N2 and are not submitted to them for a manually check ($\beta = 20\%$, error type 2) and how many ratings matched, but are submitted to the N1 and N2 for a manually check ($\alpha = 5\%$, error type 1). Follow hypothesis was defined for the significance test: H_0 : the ML rated the drawing equal to the neuropsychologist. H_1 : the ML rated the drawing not equal to the neuropsychologist.

Table 3. Significance test of N1 <-> ML (left) and N2 <-> ML (right).

	H ₀	H ₁		H ₀	H ₁
H ₀	63.0%	19.7%	H ₀	68.9%	13.4%
H ₁	9.5%	7.9%	H ₁	9.8%	7.9%

The error type 1 (cell H_1 / H_0) is on both significance tests over the 5% and not significant. The ML rated 9.5 / 9.8% of the drawings equal to N1 / N2, but with a reliability below the threshold. So those drawings have to be rated manually from a neuropsychologist.

The error type 2 (cell H_0 / H_1) should be as low as possible, because these drawings are not submitted to the neuropsychologist for a manually rating, although they are wrongly assessed. But as we can see, the error type 2 is in both cases under 20%, so β is significant.

Table 4. Overview comparison N1 with ML algorithm and N2 with ML algorithm with threshold of 0% and 78.8%.

	N1 <-> ML		N2 <-> ML	
Threshold (%)	0	78.8	0	78.8
Agreement (%)	72	80.3	79	86.6
Agreement (K)	0.45	0.62	0.56	0.73

4. Discussion

With our results is it possible to execute the BVMT-R Test in a digital way. The rating of the drawings is given by a trained ML algorithm either in a full automated way, or in

a semi-automated way with the possibility to set a threshold value for the reliability of the rating under which the drawing is manually rated by a neuropsychologist.

The biggest challenge to answer the research question was to determine the quality of the ratings received in the test data because there are no rated reference data sets (gold standard rating). With our solution, to measure the matches of the ratings of the test data performed by the COGITO GmbH with the ratings of the University Hospital Zurich, and find out it was 81%, we were then able to compare the results obtained in automated or semi-automated way with our ML algorithm with the results of either one of two neuropsychologists (N1 and N2), results with N1 showing the internal and N2 the external validation.. Consequently, to answer the research question positively the rating of the ML algorithm had to reach at least the same matching as the two professional raters.

With this result it is conceivable to create further projects in this area of science. A more detailed consideration could be a completion of the entire digital BICAMS test set using ML.

In summary, a semi-automated rating with the use of ML algorithms of patient-drawn drawing is possible. The deviation of this solution (matching 80.3% and 86.6% with the two neuropsychologists) is in the same range as the deviation between those two independent professionals (matching of 81%).

Abstract. Social determinants of health (SDoH) are the complex set of circumstances in which individuals are born, or with which they live, that impact their health. Integrating SDoH into practice requires that information systems are able to identify SDoH-related concepts from charts and case notes through vocabularies or terminologies. Despite significant standardisation efforts across healthcare domains, SDoH coverage remains sparse in existing terminologies due to the broad spectrum of this domain, ranging from family relations, risk factors, to social programs and benefits, which are not consistently captured across administrative and clinical settings. This paper presents a framework to mine, evaluate and recommend new multidisciplinary concepts that relate to or impact the health and well-being of individuals using a word embedding model trained from a large dynamic corpus of unstructured data. Five key SDoH domains were selected and evaluated by domain experts. The concepts resulting from the trained model were matched against well-established meta-thesaurus UMLS and terminology SNOMED-CT and, overall, a significant proportion of concepts from a set of 10,000 candidates were not found (31% and 28% respectively). The results confirm both the gaps in current terminologies and the feasibility and impact of the methods presented in this paper for the incremental discovery and validation of new SDoH concepts together with domain experts. This sustainable approach facilitates the development and refinement of new and existing terminologies and, in turn, it allows systems such as Natural Language Processing (NLP) annotators to leverage SDoH concepts across integrated care settings.

Keywords. Social Determinants of Health, Terminologies, Vocabularies

1. Introduction

Throughout human societies, health and illness are not homogeneously distributed due to disparities in social and economic aspects. The aspects that underpin such disparities are commonly referred to as the Social Determinants of Health (SDoH) and examples include intangible factors such as “political, socioeconomic, and cultural constructs, as well as place-based conditions including accessible healthcare and education systems, safe environmental conditions, well-designed neighbourhoods, and availability of

healthful food” [1]. The significant impacts on health and costs associated with SDoH have been reported [2] and in order for social aspects to be best utilised for service evaluation or outcome assessment and improvement, this information should be routinely collected by organisations across the integrated care continuum. However, despite technological advances, SDoH information is neither routinely nor systematically collected in Electronic Health Records (EHRs) and lacks standardisation [3,4]. The US Institute of Medicine was among the first to identify SDoH domains and recommend they be routinely collected and made available in EHRs [3]. When available, SDoH information is often stored in natural language as part of unstructured case notes which further hinders efforts to identify cases and select cohorts. Terminologies and meta-thesaurus such as SNOMED-CT and UMLS can be used to encode health-related observations or activities into a canonical form. A recent exploratory analysis [5] has confirmed the limitations of current healthcare vocabularies in documenting SDoH-related information and has called for more comprehensive, coherent, and user-friendly SDoH code sets [6] to support and facilitate the rapidly evolving health care use cases[5]. Techniques for bridging clinical and social domains using word embeddings have been proposed to explore cross-domain spaces [7] and calls for action to create standards for representing SDoH data have been suggested [3]. Recent initiatives include Health Level Seven’s (HL7) Gravity Project [8] and LOINC’s models for the representation of screening assessments and measures of SDoH [9]. Healthcare terminologies have begun adopting concepts in social domains through consultation with expert groups but sustainable processes and methodologies to support these efforts are lacking.

This paper proposes a computational approach to facilitate the process of seeking new terminology concepts as well as refreshing existing terminologies. The framework proposed in this paper leverages existing word embedding techniques [10, 11, 12] in order to mine new candidate terms from large corpora of unstructured data. Other approaches have focused on developing ontologies and taxonomies [11] yet the work presented in this paper aims to incorporate expert humans-in-the-loop in order to recommend new concepts not included in existing terminologies. This approach can also be used to refine existing terminologies with categories for specific domains.

2. Methods and Experiments

The proposed framework takes a list of seeded terms as input and returns a list of relevant concepts with domain categories assigned. This process relies on training a model to discover relationships between terms in relevant corpora and is supported by a human-in-the-loop evaluation step to ascertain the relevance of the discovered terms. Framework steps are summarised in Figure 1 and described in detail in the next sections.

Figure 1. Proposed framework for recommending new terminology concepts.

Training a comprehensive SDoH model requires a list of relevant seeded term(s) for the first iteration of the process. Together with domain experts (DEs), 57 distinct seeded terms were selected for our experiments. The terms were extracted from relevant literature definitions of SDoH (WHO, Marmot & Wilkinson [13], CDC, Wikipedia).

2.1. Data Sources and Preprocessing

The first step consists of obtaining a corpus of unstructured data suitable for model training. A collection of case notes may be obtained from EHRs, case notes, books, or other sources of knowledge. Data sources should ensure coverage of the relevant domain areas in the seeded terms and this can be achieved in consultation with the DEs.

In order to train the comprehensive SDoH model presented in this paper, we prepared a corpus of text by crawling the set of Wikipedia pages hierarchically linked through DBpedia's taxonomy to the seeded terms. We curated the collected corpus by removing irrelevant pages, and obtained 2,134 distinct pages, with 3,282,508 non-unique terms. Finally, we pre-processed the collected corpus by removing metadata, images, and tables, and by applying lemmatisation and filtering of non-textual characters.

2.2. Model Training and Model Evaluation

This step focuses on the application of word embedding techniques on the prepared corpus of text. The purpose is to train a model able to capture contextual similarities between terms and term classes. The SDoH model was built using state-of-the-art embedding techniques to discover domain-specific n-grams from the corpus of text [10]. We trained a skip-gram model with negative sampling and subsampling of the frequent words in the training corpus. Experiments to tune the model hyperparameters were undertaken and found 100-dimension embeddings, computed with a context window of 5, and n-grams of size 3, provided a rich domain representation for our task. Other techniques such as pre-trained word embedding models may be used in this step yet these typically only yield unigrams. The resulting trained model contained 77,232 terms.

For evaluation, the DEs selected five terms each defining specific SDoH domains of interest: *Housing*, *Criminal Justice*, *Financial Services*, *Health Behaviours* and *Homeless*. For each of the five terms, a set of similar (candidate) terms was computed by selecting the closest 2000 neighbours in the model's high-dimensional space using Euclidean distance. The ranked set of 2000 candidate terms was considered large enough to be evaluated by DEs in a timely manner. The set was later randomised for the DEs.

2.3. Filtering and Expert Validation

In the filtering step, candidate terms from each of the five domains of interest were programmatically checked against UMLS and SNOMED-CT terminology. Each term was labelled as *matching* when either a partial or exact match was found in the terminology (via its API), or *no match*. It is possible to use more complex matching algorithms and to filter out terms that already exist in terminologies (e.g. synonyms), however, for the purpose of developing and evaluating the framework proposed in this paper, no filters were applied, and partial and exact matching were combined.

The Expert Validation step consists of gathering information from DEs about the candidate terms' relevance in their specific domains. This was achieved by carrying out

90 minute workshop sessions with social workers where at least 3 different DEs of the same specialty evaluated the same set by responding *accept*, *reject* or *pass* for each term.

2.4. Inter-Rater Evaluation and Recommendation of New Concepts

In this step the results are analysed in order to determine consensus among DEs (inter-rater agreement based on simple majority was used due to small number of DEs, however, other methods are possible). Decisions are made for all candidate terms and a curated list of recommended new concepts is the output of the framework (Figure 1). This list may serve to refine the input list of seeded terms in order to further build or refine models.

3. Results and Discussion

The framework proposed in this paper enabled the training of a model based on SDoH seeded terms. The model was evaluated on five key SDoH domains through workshops with DEs (each domain seen by 3 distinct DEs with the exception of *Housing*). Figure 2 summarises the DEs evaluation results for each domain and depicts a trend where lower ranked terms were accepted less often than those nearest to each of the five domain terms.

Figure 2. Proportion of terms accepted by DEs. For each domain, terms were ranked using Euclidean distance in the SDoH embedding model high-dimensional space.

Table 1 shows the results of matching each of the terms against SNOMED-CT and UMLS. Overall our findings show a large number of new terms that did not match either (on average 76% in SNOMED-CT and 83% in UMLS), with SNOMED-CT showing a better coverage throughout. Across all domains, on average, 40% of terms are accepted by DEs consensus of which 30% of them were not found in either (no match). *Financial Services* was the domain with most new relevant terms found across both SNOMED-CT (48%) and UMLS (50%) suggesting this area may be most lacking. *Housing* and *Homeless* are the two domains with the least number of new terms found and accepted by DEs (respectively 16% and 23% for SNOMED-CT, and 19% and 30% UMLS). Out of all 10,000 terms evaluated in this paper, the framework yielded 30% as concepts to be suggested for inclusion in terminologies and highlights terms from other terminologies of relevance to this domain. A limitation of the modelling approach is yielding less relevant n-gram combinations (e.g. ‘housing provides’ versus ‘housing programs’). However, the human-in-the-loop step helps filter out such cases. A subset of the concepts found could also be synonyms of existing terminology concepts and terms could appear

in both UMLS and SNOMED-CT. Since no partial or exact matches were found, however, it is still relevant to suggest bringing these terms in to terminologies.

Table 1. Results of matching terms against SNOMED-CT and UMLS.

Domain	SNOMED-CT				UMLS			
	Match % (N)		No Match % (N)		Match % (N)		No Match % (N)	
	Accepted	Rejected	Accepted	Rejected	Accepted	Rejected	Accepted	Rejected
Housing	8.50% (170)	25.75% (515)	16.15% (323)	49.60% (992)	6.05% (121)	17.80% (356)	18.60% (372)	57.55% (1151)
Criminal Justice	9.95% (199)	5.75% (115)	24.30% (486)	60.00% (1200)	7.55% (151)	3.75% (75)	26.70% (534)	62.00% (1240)
Financial Services	9.40% (188)	3.40% (68)	47.80% (956)	39.40% (788)	7.65% (153)	4.20% (84)	49.55% (991)	38.60% (772)
Health Behaviours	10.85% (217)	11.15% (223)	27.70% (554)	50.30% (1006)	6.80% (136)	7.50% (150)	31.75% (635)	53.95% (1079)
Homeless	19.30% (386)	17.25% (345)	23.05% (461)	40.40% (808)	12.75% (255)	10.90% (218)	29.60% (592)	46.75% (935)
Total (Average)	11.60%	12.66%	27.80%	47.94%	8.16%	8.83%	31.24%	51.77%
	24.26%		75.74%		16.99%		83.01%	

4. Conclusions

The lack of standardisation, terminologies and code sets in complex multidisciplinary domains remains a barrier to the successful documentation and use of SDoH in practice. This work assessed the coverage of existing terminologies in selected SDoH domains using expert humans-in-the-loop and proposed a framework for the discovery of SDoH concepts from unstructured data. Further work is needed to refine model training, to include additional categories for DEs to assign to terms and allowing new term/code sets to be defined in the process, and to inspect SDoH in other terminologies (e.g. ICD-11).

Abstract

This paper presents an original machine learning method for extracting diagnostic medical information from heart sound recordings. The method is proposed to be integrated with an intelligent phonocardiography in order to enhance diagnostic value of this technology. The method is tailored to diagnose children with heart septal defects, the pathological condition which can bring irreversible and sometimes fatal consequences to the children. The study includes 115 children referrals to an university hospital, consisting of 6 groups of the individuals: atrial septal defects (10), healthy children with innocent murmur (25), healthy children without any murmur (25), mitral regurgitation (15), tricuspid regurgitation (15), and ventricular septal defect (25). The method is trained to detect the atrial or ventricular septal defects versus the rest of the groups. Accuracy/sensitivity and the structural risk of the method is estimated to be 91.6%/88.4% and 9.89%, using the repeated random sub sampling and the A-Test method, respectively.

Keywords. Time growing neural network, Intelligent phonocardiography, A-Test method, septal heart defects, heart sound signal

1. Introduction

Since the last few decades when extracting medical information from heart sound has become a topic of study, several machine learning methods have been proposed for learning details of the heart sound signals for the classification purposes [1][2][3]. Although deep learning methods initiated a considerable change in the processing methods sophisticated for medical signals including heart sound signal [4][5], several research questions should be answered in terms of both the theoretical and the applicative contents. PhonoCardioGram (PCG) is a device for recording of mechanical activity of heart, as reflected by the heart sound. The term Intelligent PhonoCardioGraphy that has recently appeared in this contexts, implies on a computerised PCG supported by the intelligent machine learning

¹Corresponding Author: Arash Gharehbaghi, Department of Innovation, Design and Technology, Mälardalen University, Västerås, Sweden; E-mail: arash.ghareh.baghi@mdh.se.

methods to extract medical information from the signal [6][7][8]. Time Growing Neural Network (TGNN) has been introduced as a powerful learning method either for classifying cyclic time series [4], or for extracting medical information from the non-cyclic stochastic time series [5], in parallel to the hybrid methods [9][10][11]. Effectiveness of TGNN has been investigated for symptom detection of PCG signals, and also for screening a certain heart abnormality among other possible pathologies [11][12][5]. An important applicative aspect of IPCG is its potential in patient prioritisation in terms of the disease severity. For example, a valvular regurgitation in children is managed differently from septal leakage, as the former might not effect growth of the children, whereas the later which can effect growth of the patient.

This paper presents a method for diagnosing a group of paediatric patients with septal defect from the other group of valvular leakage, the two pathological conditions manifested by systolic murmur. Similarity of the disease manifestations in auscultation make the diagnosis a complicated task, which necessitates expensive investigations even for those with mild defects. It is important to note that timely detection of septal defects can prevent further complications including pulmonary artery defect, ventricular hypertrophy and dilatation, pulmonary hypertension, and heart failure, each can put negative impact on the growth of the children suffering from, which is sometimes irreversible. The presented method employs TGNN for extracting medical information from a heart sound recording regarding the heart septal defects, showing an important application of medical informatics. The resulting technology can be easily incorporated into an IPCG to help practitioners or nurses at primary healthcare centres to detect and prioritise the patients for further investigation. The resulting IPCG can provide valuable medical information even for a paediatric cardiologist to be oriented in the echocardiographic investigation [13].

2. Material and Methods

2.1. Data Collection

Heart sound signals of 10 second duration were recorded from the children referrals to Tehran University of Medical Sciences, using a WelchAllyn Meditron Analyzer in conjunction with a portable computer with 44100 Hz of sampling frequency and 16 bit resolution. All the referrals or their legal guardians gave the informed consent for participation in the study, which was conducted according the Good Clinical Practice, and complied with the World Medical Association and Helsinki Declaration. The referrals were investigated by a paediatrician as well as paediatric cardiologist who used echocardiography as the gold standard along with complementary tests like chest X-Ray, in accordance to the guideline of Tehran University of Medical Sciences. Six groups of paediatric individuals were included in the study: healthy children with no audible murmur (NM), and with audible innocent murmur (IM), as well as abnormal children with Ventricular Septal Defect (VSD), Atrial Septal Defect (ASD), Mitral Regurgitation (MR) and Tricuspid Regurgitation (TR). The patient population is listed in Table 1.

Table 1. Study population.

Heart condition	Number of Patients	Age Range (years)	Average age \pm SD (years)
ASD	10	5 – 15	9.3 \pm 3.2
IM	25	2–14	6.7 \pm 3.7
NM	25	4 – 15	8.6 \pm 3.4
MR	15	4 – 18	11.8 \pm 4.1
TR	15	6 – 18	12.6 \pm 4.4
VSD	25	1 – 9	3.9 – 2.4

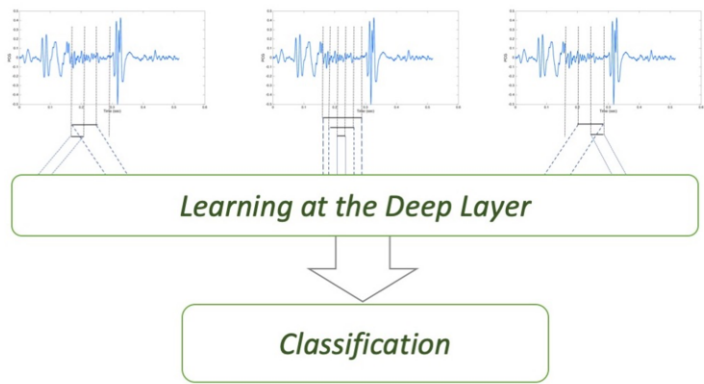

Figure 1. The flowchart of the learning method.

2.2. The processing algorithm

The signals are first down-sampled to 2 KHz using the antialiasing low-pass filter and then normalised. The processing method is based on our deep learning method, in which spectral contents of heart sound signal is calculated using three fashions of growing windows. In this technique, the systolic part of PCG signals are characterised by its spectral contents calculated over three different schemes of temporal windows: the forward, the backward and the mid-growing windows. Details of the growing method can be found in [4]. The number of the growing windows for each scheme is selected to be 3 based on the medical considerations. Figure 1 illustrates the growing time schemes. We used Fisher criteria for finding the most discriminative frequency bands for spectral calculation. This is performed at the deep learning layer in which the most discriminative frequency band is found for each temporal window, and the spectral energies are used by a three layer perceptron neural network with a hidden/output layer of 10/1 neurone for the ultimate learning process. The neural network is trained using back propagation error method in which the output layer performs the binary classification of septal defect against the rest of the classes .

Figure 2. Results of the A-Test method for different index of k -value.

2.3. The validation method

The method is validated by using repeated random sub-sampling method as well as the A-Test for the structural risk evaluation. In the repeated random sub-sampling, 30% of data is randomly selected for testing and the rest for training the method, and the two performance measures, accuracy and sensitivity, are calculated, where the former is defined the percentage of the correctly classified samples whereas the later which is defined as the percentage of the correctly classified samples from the patient group (those patients with septal defect). This procedure is repeated several times and the statistical descriptive of the performance measures are found. The A-Test method is based on using K-fold validation method with different values of K , spanning from 2 to half of the minimum group size [4].

3. Results

The repeated random sub-sampling with 100 iterations was applied to validate performance of the method. Average of the accuracy and the sensitivity is estimated to be 88.4 and 91.6 with and standard deviation of ± 3.9 and ± 5.7 , respectively. In order to evaluate structural risk of the method, the A-Test method is employed. The average classification error is estimated to be 9.89% using the A-Test method. Figure 2 shows results of the A-Test method, exhibiting a decreasing trend for the classification error, which implies on a good capacity of enhancement with larger training data. As can be seen, the method performance is by far better than a paediatric cardiologist who relies on the conventional auscultation, as the studies show the average screening accuracy is less than 80% [3].

4. Discussion

This study suggested a method for distinguishing two important cardiac abnormalities, the septal defects and valvular regurgitation. Ventricular septal defects must be diagnosed at the early ages, and the diagnosed patients should undergo appropriate disease managements, in contrast with the valvular regurgitation which are found at the later ages of the childhood. An important aspect of this study is the use of sophisticated time grow-

ing neural network for characterising heart sound signal, and hence extracting important medical information from the signals. This innovative method allows the IPCG to provide a more comprehensive information to practitioners or family doctors at primary healthcare centres, resulting in a more efficient patient prioritisation. This avails access to paediatric cardiologists to those of rather urgent need sooner than those of need to a regular supervision, and also improves automatic extraction of medical information from IPCG.

Acknowledgement

The authors would like to thank Prof. A. Kocharian for his valuable cooperation in data collection. This study was supported by the CAPIS Inc., Mons, Belgium, and also by the KKS financed research profile in embedded sensor systems for health at Mälardalen University, Västerås, Sweden.

Abstract. In general, small-mid size research laboratories struggle with managing clinical and secondary datasets. In addition, faster dissemination, correlation and prediction of information from available datasets is always a bottleneck. To address these challenges, we have developed a novel approach, Document Oriented Graphical Analysis and Prediction (DO-GAP), a hybrid tool, merging strengths of Not only SQL (NoSQL) document oriented and graph databases. DO-GAP provides flexible and simple data integration mechanism using document database, data visualization and knowledge discovery with graph database. We demonstrate how the proposed tool (DO-GAP) can integrate data from heterogeneous sources such as Genomic lab findings, clinical data from Electronic Health Record (EHR) systems and provide simple querying mechanism. Application of DO-GAP can be extended to other diverse clinical studies such as supporting or identifying weakness of clinical diagnosis in comparison to molecular genetic analysis.

Keywords. Data integration, clinical trials, data quality, data processing

1. Introduction

Traditionally, to develop a relational database or data repository, first, the data requirement is analyzed and then data structure is designed based on the requirements [1]. The data structure remains rigid and can only hold the data elements that it was designed for [2]. Then, data integration is performed by feeding-in data from various sources into a data warehouse and processing it afterwards. Fixed source to target Extract Transformation and Load (ETL) processes are used to load data into a data repository [3]. Drawback of using relational databases is that it is difficult to keep up with changing data requirements and it takes months to modify source to target mapping and implement ETLs. Not only SQL (NoSQL) databases were developed to overcome fixed data structure limitation of relational data models [4].

¹ Corresponding Author, Shorabuddin Syed, University of Arkansas for Medical Sciences, Little Rock, AR, USA; E-mail: ssyed@uams.edu.

The schema-less design of NoSQL allows flexibility and scalability to add information to any field without a need to define the structure in advance compared to SQL databases [5-7]. One of the common NoSQL database is document-oriented database that uses documents as the structure for data storage and queries, document is a block of XML or JSON [7, 8]. Each document can have the same or different structure. MongoDB is one of the document-oriented database system, it is highly flexible, partition tolerant and consistent [4, 9].

Graph database models their schema as graphs, using nodes and edges. Each node represents an entity (patient, physician etc.) and they are connected by edges, representing relationship between the nodes[10]. Graph database is queried by traversing through the connected links. The graph database are expressive and can be easily conceptualized making them an ideal choice to adopt for data analysis[10]. Moreover, “graph databases excel in traversal-type queries ”[11], they facilitate deep knowledge discoveries using simple-to-mid complex queries. Neo4j (www.neo4j.com) is a graph database designed to manage information with graph-like nature.

DO-GAP attempts to take advantages of both the models (Document and Graph DB) and solves challenges (i) flexible schema that enables faster and more iterative development, and scalable databases (ii) clean and readily available data for graph database. DO-GAP uses MongoDB as document-based data repository and Neo4j graph database for simple analysis and easy visualization.

2. Methods

To address our hypothesis, a pipeline was built for processing of the incoming data, store it in primary data repository, cleansing and transferring study specific data to graph database for analysis and knowledge discovery as shown in Figure 1.

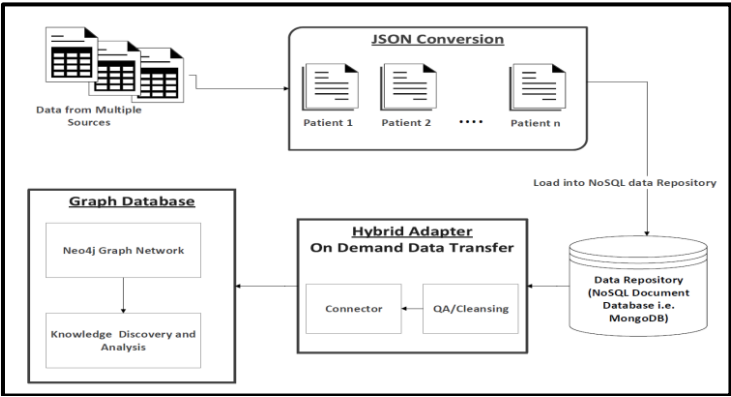

Figure 1. DO-GAP Architecture.

2.1. Data Architecture

The flow starts by collecting and assembling data from multiple sources, extract patient’s longitudinal data from the source files and create a JSON document for each patient. The

JSON files created will be merged into primary data repository, MongoDB. On-demand, study-specific data from MongoDB is cleansed and transferred to graph database, Neo4j. Laboratories may receive clinical and biological data from multiple sources in different format, frequency and file types. Metadata, a mapping document, for each source file is created to standardize the source data elements. JSON conversion tool creates a JSON document based on source and metadata files. The conversion is independent of source file format, thereby minimizing data pre-processing time. Figure 2, shows an example of patient demographic Comma Separated Values (CSV) file and its equivalent JSON file created using the JSON conversion tool. A master metadata file is maintained during the process.

Example Patient demographics file
id,full_name,age,Gender,ethnicity,DOB,DOD,alive_Dead,Zipcode,mrn,race 109563,Jon Doe,68,Male,Non-Hispanic or Latino,5/1/1951,NULL,Y,72207,M000501,White
Example standardization Patient demographics file
{ "patient_id":109563,"patient_name": "Jon Doe","age":68,"sex": "Male","ethnicity": "Non-Hispanic or Latino","birth_date": "1/1/1990","death_date": null,"is_alive_yn": "Y","zip": 72207,"mrn": "M000501","race": "White" }

Figure 2. A sample demographic file and its equivalent standardized JSON file.

The JSON documents created are loaded into NoSQL document database i.e. MongoDB, using its native data import tool. To inform researchers on the available data fields in DO-GAP, a list of all field names (i.e. Keys) present in the MongoDB and their description is available. This list is updated when new data elements are imported into the database. Researchers can select from the available fields for data extraction and analysis.

Based on user selection, Hybrid adapter cleanses the selected data elements. The cleansing process includes applying standard rules such as removing potential duplicates and null values etc. This cleaned data set will be fed to Connector, it unwinds JSON documents and stores it as deconstructed array document using \$unwind, \$project, \$out MongoDB operators[4]. The deconstructed array document is then written to CSV file using mongoexport utility. Connector uses the generated CSV files to create nodes in Graph database i.e. Neo4j, and builds relationship between the nodes. By this approach only required data elements for a study is selected on-demand, cleansed and made available as a new study in graph database. Thereby overcoming Graph database’s data quality and volume limitations[12]. In Graph database component, the data extracted from MongoDB is loaded into Neo4j and is analyzed using native tools such as Neo4j browser and Bloom [13].

3. Application

About 2,300 patients with any type of lung cancer disease[14] were chosen for the study. Selected patient’s clinical facts, genomic profiles, comorbidities, social and family history were loaded into DO-GAP for knowledge discovery, resulting in 2,760 nodes and 9,683 relationships. We ran a Cypher query to find the common gene alterations in our sample. As shown in Figure 3, most patients have gene TP53 and LRP1B, TP53 and SPTA1 alterations. Cypher queries are simple to learn as non-technical users can query the database by conceptualizing the graphs, which is difficult with relational databases.

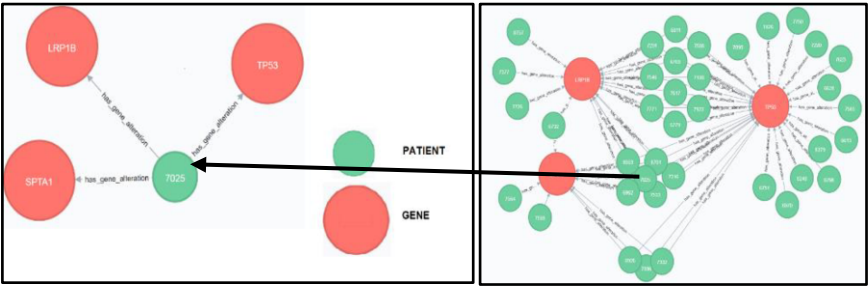

Figure 3. Partial graph showing links between Patient and their Gene alteration.

The output of graph analysis heavily depends upon connectivity between nodes [15], in DO-GAP we can click on any two gene nodes and can ask for common patterns (clinical facts) between them. Graph traverse through all links and displays every node (clinical facts) that is connected to these two gene nodes, hence the data or knowledge discovery.

Graph database can be queried using native visualization tools of Neo4j. In our case, we have used Bloom [16] to demonstrate the ease of querying. As shown in Figure 4, a simple English-like querying language syntax is used to find all patients with any gene alterations and are smokers. In addition, it displays the profile of query results, for example in Figure 4; we have 43 patients that are smokers with at most 10 gene alterations. Graph database query can be expanded to include other clinical facts along with gene information.

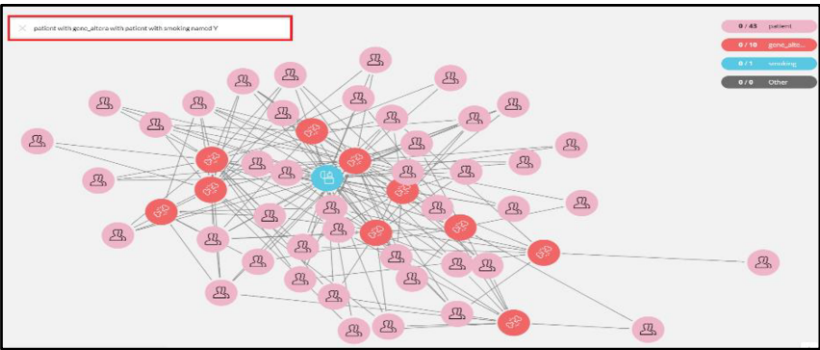

Figure 4. Very simple query to find patients who are smokers and has gene alteration.

4. Discussion and Conclusion

DO-GAP offers hybrid and flexible data integration, expansion, productive data analysis and prediction with minimal coding. Advantage of using DO-GAP is twofold (1) flexible schema that enable faster and more iterative development, and scalable NoSQL databases. (2) As strength of graph data analysis heavily depends on quality of data, we have achieved it by using hybrid adapter that automatically cleanse user selected data and import to graph database. Graph databases reduces query complexity compared to

both relational and MongoDB databases. Use of graph database reduces data analysis and data inference time; we have demonstrated this by two basic use cases (i) common gene alteration, and (ii) simplicity of querying heterogeneous data. As this was a pilot study, we selected the use cases that profile the data, which is the first step in research data analysis.

There are several limitations in this study that we wish to acknowledge. First, to resolve identity of individuals, i.e. entity resolution, which is a complex process in itself and is beyond the scope of this paper. Currently, DO-GAP process these records as separate subjects, in future, an entity resolution systems such as OYSTER [17], can be employed to resolve this limitation. Second, the cleansing component of hybrid adapter only checks for null values and duplicate clinical facts, but can be expanded to incorporate in-depth data quality checks. Finally, results of selected use cases can be easily reproduced using relational databases by technical users. However, DO-GAP was designed to be a data management and analysis tool for non-programmers such as lab technicians, for whom conceptualizing relational database schema and building appropriate queries is challenging task. This pilot project, paves way for future work that will seek to address in-depth graph queries for better findings and correlations. We envision to address aforementioned limitations in our future work that will empower users to explore critical insights which is currently not available.

Funding Acknowledgment and Consent: Patients data used were obtained under IRB approval (IRB#202880) at the University of Arkansas for Medical Sciences (UAMS). The study was supported partly by the Seeds of Science Grant by the Winthrop P. Rockefeller Cancer Institute.

Electronic Whiteboard in the Inpatient Care Management: Nurses' Perceptions About the Use

Liliana GIRALDO^{a,1} Bibiana SCHACHNER^a, Daniel LUNA^a, Sonia BENITEZ^a

^aDepartment of Health Informatics, Hospital Italiano de Buenos Aires

Abstract. In the hospital setting, the traditional method of information for nurses is to consult the Electronic Health Records (EHR) on several occasions to check the continuous updates of the prescriptions. This process, in practice, involves time and multiple setbacks such as: availability of equipment (there is no computer per nurse in the office), number of patients assigned (it involves entering each EHR one by one). This is how the implementation of the tool known as electronic whiteboard (e-whiteboard) came about. The aim of this study was to explore perceptions of nurses after implementation of e-whiteboard, recently introduced at Hospital Italiano de Buenos Aires. A Qualitative study, which consisted of 5 group interviews with a total of 27 participants. A convenience sampling was used (selection of nurses from different shifts), corresponding to 4 sectors of adult patient admissions and 1 sector of pediatric patients. The main findings were positive aspects such as: it was a simple, intuitive and easy to navigate interface, it allowed communication with other health professionals (physicians, nutritionists and kinesiotherapists), and it facilitated the visualization of real time information that favors the fulfillment of tasks in scheduled time. This tool is considered of great clinical importance for coordinated patient care because the visibility and availability of clinical information improves communication between professionals, streamlines workflow, and consequently accelerates shared decision making.

Keywords. Perceptions, nursing, electronic whiteboard, inpatient

1. Introduction

Advances in health have led organizations to incorporate technologies for patient care planning [1]. In the hospital setting, during the hospital stay, nursing work regarding patient care planning requires continuous updates. The traditional method, which consists of accessing the Electronic Health Records (EHR) involves multiple setbacks [2] such as: availability of equipment (there is not one computer per nurse in the office), or the number of patients assigned (it implies gaining access to every EHR one by one). Unlike EHR, electronic whiteboards (e-whiteboards) are being used as a tool to monitor [3,4] and improve the quality and safety of care [4].

Previous research has shown that e-whiteboards have certain advantages over traditional dry erase white-boards [5,6] (which have been and continue to be used in

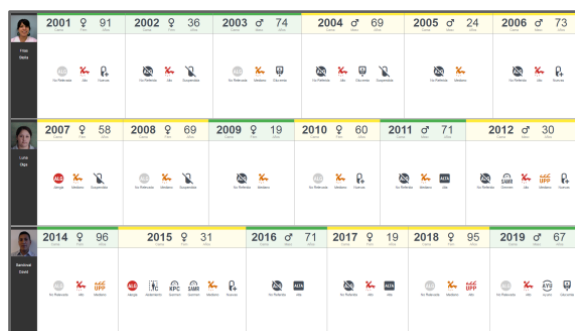

¹ Corresponding Author, Liliana. Giraldo. BSN. Department of Health Informatics, Hospital Italiano de Buenos Aires, Perón 4190, Buenos Aires (1199), Argentina. Email: liliana.giraldo@hospitalitaliano.org.ar

our local environment). These advantages include automated updating of patient information, the ability to visualize information in real time, and integration with other clinical information systems, and reduction of the workload of nurses [2,7]. While the use of tablets and mobile solutions in hospitals is currently being discussed, in our environment we are using more precarious tools and are just introducing e-whiteboards [4]. The aim of this study was to explore perceptions of nurses after implementation of e-whiteboard, recently introduced.

2. Methods

The Hospital Italiano de Buenos Aires (HIBA) is an institution with more than 1200 nurses and 750 beds in Buenos Aires, Argentina. The e-whiteboards, large electronic screens located on the nurse's station wall and out of sight of patients and visitors, were implemented in October 2017. This implementation were restricted to the adult and pediatric inpatient wards.

The e-whiteboard was developed with a user-centred design methodology, with a system that makes "retrieval information" in real time, addressed to nursing care staff. Categorization of information are displayed in around 84 icons in a horizontal distribution. The categories are: hospitalization data (patient's patronymic data, bed number, gender, age), alerts (for example: new prescriptions and/or changes in medication, isolation status, allergies), risks (pain scale assessment, pressure ulcers) and tasks (laboratory requests, patient transfers). The system interacts with the data from the admission, discharge and transfer (ADT) system, operating room agenda, EHRs, medical prescriptions and Computerised Physician Order Entry (CPOE) for complementary tests, nursing e-chart. (See Figure 1).

Figure 1: e-whiteboard screen

2.1 Design

A qualitative study to explore perceptions of nurses after implementation of e-whiteboard [8] was performed using group interviews. The data obtained, were homogeneous in terms of the institutional hierarchical position, there were not an inhibition of free expression by power relations and / or hierarchy, and it was achieved a greatest diversity of possible opinions.

A convenience sampling was carried out that included the selection of nurses from different shifts (morning, afternoon, evening and Saturday, Sunday or holiday). These Nursing staff belonged to four adult wards and one pediatric ward. From March to April 2018, 5 group interviews were conducted, with a duration of 90 minutes each one following an open-ended questionnaire. Grounded theory was used to analyze the transcribed data and build convergent themes. The relevance and importance of themes was constructed by examining frequency, convergence, and intensity. The presentation of results is oriented by these categories.

3. Results

A total of 27 nurses, with no age limit, from both genders, and from the general hospitalization area, participated in different shifts. Those nurses who carried out administrative management tasks (not patient care) were excluded. Six dimensions emerged from this study: use, communication, workflow, data quality, training and technical support. Each dimension is detailed with its respective findings (See Table 1).

Table 1. Dimensions and findings

Dimension	Description	Example
Dimension one: Use	Two components were identified: interface design and information availability. Nurses' perceptions were positive in relation to a simple and intuitive interface, simple navigation based on user-centered design guidelines, and the interaction with other systems of the institution. Likewise, it was highlighted that the iconography used facilitates its interpretation and use. In this sense, the most used icons were: assessment of pain scale, fall risk, isolation status, early warning, diet and the status of pharmacological prescriptions (new, modified, and suspended).	<i>"I use the e-whiteboard to visualize the pending tasks and for patient care planning"</i> <i>"It's very complete, because it shows everything you need to plan patient's care"</i>
Dimension two: Communication	Four structural elements of communication were determined using group interviews: the e-whiteboard properties, its physical location, permanent visualization, and the health personnel that must interact with the e-whiteboard (nurses, nutritionists, kinesiologists, stretchers, physicians, among others). Although they expressed positive perceptions related to the communication established with other health professionals (physicians, nutritionists and kinesiologists), it was not useful for the communication between them (nursing staff) to perform the shift pass.	<i>"It is very useful for communication with nutritionists and kinesiologists who come to evaluate patients"</i> <i>"Allows easy identification of the nurse in charge of the patient"</i>
Dimension Three: Workflow	A perception of a workflow improved was identified, related to: decrease of constant EHR access, visualization of relevant information and pending tasks in real time, and facilitates fulfilling tasks in scheduled time (without delays, improving timely patient care).	<i>"When there are changes in medical indications, they are immediately visualized, this helps to better plan our routine"</i>
Dimension Four: Data	The interviewees expressed positive aspects related to: the accuracy, reliability and quality of the information	<i>"It is reliable and secure data that are displayed on</i>

quality	displayed. They emphasized the capability to carry out patient care planning (due to the accessible and timely information), without generating complex processes to understand and assimilate the meaning of the data through iconography and colors.	<i>the e-whiteboard"</i>
Dimension Five: Training	The nurses mentioned as a positive aspect, the brochures provided with the information of the e-whiteboard. However, they consider negative the lack of training or follow-up during the implementation.	<i>"The information displayed is easily understood, but I would have liked accompaniment in my hospital sector"</i>
Dimension Six: Support	They mentioned as a negative aspect the lack of a help desk support that would allow the resolution of problems related to the e-whiteboard, and difficulties when the board failed.	<i>"When a e-whiteboard failed, we didn't know what to do"</i>

4. Discussion

This research proposed to explore the perceptions of nurses in relation to the implementation of the e-whiteboard. The main findings were positive aspects such as: the e-whiteboard was a simple, intuitive and easy to navigate, allowed communication with other health professionals (physicians, nutritionists and kinesiologists), and facilitated the real time visualization of information that favors the fulfillment of tasks in a scheduled time. The most used icons were: pain scale assessment, fall risk, isolation, early warning, diet and the status of pharmacological prescriptions.

This system is considered important for a coordinated patient care because the visibility and availability of clinical information improves communication between professionals, streamlines workflow [8], and consequently speeds up shared decision-making. Consistent with other studies [3,9], the e-whiteboard represents a technology that improves communication and coordinated patient care. On the other hand, the interviewees expressed certain negative aspects such as: it was not useful for communication between nursing staff to carry out the shift pass, the lack of training or coaching in its use, or the lack of a convenient support. In view of these findings, training and information dissemination should be planned in order to proceed in case of failure or to mitigate the risk.

The e-whiteboard could not be incorporated in the nursing pass workflow due to its physical location in the nursing office. The system could be viewed from the corridors by family members. Because information that must be hidden to maintain patient confidentiality (for example: sex, gender and other important clinical history), and after a consultation with the legal department, it was decided to use the bed numbers instead of the patient's name or initials.

Despite this is a unicentric study, the user-centered design methodology used facilitated the resolution of some specific needs of the end user, providing satisfaction and a good experience [10]. Post-implementation, the acceptance of the system by the staff is decisive [11], which has a direct impact on its use.

We believe that our findings can provide an approach to the understanding the complex factors related to the implementation of health technology, looking at staffs needs and concerns that are still present post-implementation [12], and which will be

worked on in future studies. This information is useful and can be expanded through a multi-hospital study.

Abstract. Biomedical research has become data-driven. To create the required big datasets, health data needs to be shared or reused out of the context of its initial purpose. This leads to significant privacy challenges. Data anonymization is an important protection method where data is transformed such that privacy guarantees can be provided according to formal models. For applications in practice, anonymization methods need to be integrated into scalable and robust tools. In this work, we focus on the problem of scalability.

Protecting biomedical data from inference attacks is challenging, in particular for numeric data. An important privacy model in this context is t -closeness, which has also been defined for attribute values which are totally ordered. However, directly implementing a scalable algorithmic representation of the mathematical definition of the model proves difficult. In this paper we therefore present a series of optimizations that can be used to achieve efficiency in production use. An experimental evaluation shows that our approach reduces execution times of anonymization processes involving t -closeness by up to a factor of two.

Keywords. data protection, anonymization, inference attacks, scalability

1. Introduction

Biomedical research, e.g. in the field of precision medicine which tailors healthcare to characteristics of individuals, is increasingly data-driven and leveraging methods from data science such as machine learning [1]. However, when creating the required big datasets, stringent privacy protection is mandated by laws and regulations. Hence, a wide range of safeguards has to be applied, including organizational and technical measures.

Data anonymization is an important building block for implementing technical privacy protection. The basic idea is to transform data in such a manner that formal guarantees, e.g. regarding the risk of singling out, linkage or inference, can be provided [2]. These formal guarantees are captured by so called *privacy models*. t -Closeness is a state-of-the-art model for protecting data from inference attacks. The model requires that the distribution of sensitive attribute values in a set of indistinguishable data records is not too different from the distribution of sensitive information in the overall dataset [3].

2. Objective

The ARX Data Anonymization Tool is among the few software solutions for quantitative data anonymization, that have found wide-spread adoption. ARX focuses on data transformation methods which have been specifically recommended for applications to health data and it implements models for protecting data from singling out, linkage and inference [4]. t -Closeness is amongst the models supported.

t -Closeness has been specified in different variants that apply to variables with different scales of measure. One of these variants focuses on variables which are totally ordered. This model is particularly relevant in practice, as it is one of the few privacy models which have been proposed for protecting sensitive numeric variables.

When using ARX to protect complex datasets using the t -closeness model, however, we realized that the initial implementation is not scalable. Upon further inspection, we realized that directly implementing a scalable algorithmic representation of the mathematical definition of the model t -closeness proves difficult in general. In this paper we therefore present a series of optimizations that we have developed to achieve efficiency in productive use. All of them have been integrated into ARX.

3. Methods

3.1. Problem Definition

t -Closeness is a condition that applies to equivalence classes, i.e. groups of records which are indistinguishable regarding attributes that could be used for linking records. Let $P(e) = (p_1, p_2, \dots, p_m)$ be the relative frequency distribution of sensitive values in a given equivalence class e and let $Q = (q_1, q_2, \dots, q_m)$ be the relative frequency distribution of sensitive values in the whole dataset. $D[P(e), Q]$ is the distance between the distributions $P(e)$ and Q [3]. It is defined as follows [3]:

$$D[P(e), Q] = \frac{1}{m-1} \sum_{i=1}^m \left| \sum_{j=1}^i (p_j - q_j) \right|.$$

A dataset fulfills t -closeness with numerical ground distance if for all equivalence classes e , $D[P(e), Q] \leq t$ holds.

	Age	Sex	LoS	AdmQtrr	Charge
Class e1	[25, 50[Male	[1, 5[3	50.000
	[25, 50[Male	[1, 5[3	60.000
Class e2	[50, 75[Female	[5, 10[1	60.000
	[50, 75[Female	[5, 10[1	60.000
	[50, 75[Female	[5, 10[1	70.000

Figure 1. Example discharge dataset. "LoS" = Length of stay, "AdmQtrr" = Admission quarter.

Figure 1 shows an example dataset with a sensitive attribute "Charge" and two equivalence classes $e1$ and $e2$ defined by the values of the other attributes. The distribution of sensitive values is $Q = (\frac{1}{5}, \frac{3}{5}, \frac{1}{5})$ since the values 50.000, 60.000 and 70.000 appear 1, 3 and 1 times in the whole dataset, respectively. For the equivalence classes, we get $P(e1) = (\frac{1}{2}, \frac{1}{2}, 0)$ and $P(e2) = (0, \frac{2}{3}, \frac{1}{3})$. Consequently, we have

$$D[P(e1), Q] = \frac{1}{2}(|\frac{1}{2} - \frac{1}{5}| + |\frac{1}{2} - \frac{1}{5} + \frac{1}{2} - \frac{3}{5}| + |\frac{1}{2} - \frac{1}{5} + \frac{1}{2} - \frac{3}{5} - \frac{1}{5}|) = \frac{1}{4},$$

$$D[P(e2), Q] = \frac{1}{2}(|-\frac{1}{5}| + |-\frac{1}{5} + \frac{2}{3} - \frac{3}{5}| + |-\frac{1}{5} + \frac{2}{3} - \frac{3}{5} + \frac{1}{3} - \frac{1}{5}|) = \frac{1}{6}.$$

Hence, we can conclude that the dataset satisfies t -closeness with $t = \max\{\frac{1}{4}, \frac{1}{6}\} = 0.25$.

A straight-forward implementation of t -closeness for fully ordered attributes would implement this by checking if the following inequality holds:

$$|r_1| + |r_1 + r_2| + |r_1 + r_2 + r_3| + \dots + |r_1 + \dots + r_{m-1}| \leq t(m-1)$$

Each r_i has the form $r_i = p_i - q_i$, where p_i is the frequency of the attribute value number i in the currently considered equivalence class e of the transformed data set, and q_i the frequency of the attribute value number i in the entire input dataset.

As we will show in Section 4 this process is highly inefficient. The main reason is that it needs to iterate over all sensitive attribute values contained in the overall dataset. Given that this process needs to be executed for all equivalence classes, the worst-case complexity is $O(n^2)$ where n is the number of records in the dataset.

3.2. Optimization Approaches

In this section, we present three optimizations that we used to improve our initial, straight-forward implementation of the model.

Optimization 1 – Fibonacci hashing: The first optimization addresses the implementation level. One of the most time-consuming aspects of implementing a check for t -closeness is to dynamically group the sensitive attribute values in each class to determine their frequency. The standard data structure used for this purpose are hash tables. ARX already used an efficient implementation provided by the High Performance Primitive Collections for Java library [5]. However, these collections are still much more complex than required, as they for example support updating the data stored in a map. We therefore implemented a simplified hash table using Fibonacci hashing based on the golden ratio to reduce the number of CPU cycles required for adding and querying elements.

Optimization 2 – Check pruning: The second optimization addresses the mathematical definition of the model. Let us assume that the attribute values number $1 \dots k$ in the equivalence class currently under consideration do not occur at all, then $p_1 = p_2 = \dots = p_k = 0$ holds and the first k summands in the above condition have the form:

$$|-q_1| + |-q_1 - q_2| + \dots + |-q_1 - \dots - q_k|.$$

This partial sum depends only on the input dataset and can therefore be pre-calculated for every possible value of k before the individual equivalence classes of the transformed dataset are checked.

These precalculations can be performed in an initialization step, for ascending values of k until the corresponding subtotal is greater than the threshold, i.e. the following holds:

$$|-q_1| + |-q_1 - q_2| + \dots + |-q_1 - \dots - q_k| > t(m-1).$$

Let us denote the smallest value of k for which this inequality is fulfilled with x .

When checking whether t -closeness holds for a specific equivalence class, as a first step, we calculate the smallest index of any attribute value occurring in the class. We call this index y . When $y > x$ it can be inferred that the following summands are included in the relevant sum:

$$|-q_1| + |-q_1 - q_2| + \dots + |-q_1 - \dots - q_x|.$$

It follows that the threshold $t(m-1)$ will definitely be exceeded and computations can already be stopped at this point (concluding that privacy guarantees are not fulfilled).

Optimization 3 – Summand pruning: The third optimization adds an additional pruning mechanism using pre-computations.

It can be used in cases where the pruning strategy described above is not applicable, i.e. if $y \leq x$ holds. It works by starting the summation at position y , using an appropriate sum which has been pre-calculated ahead of time for all $k \leq x$ as a starting point:

$$|-q_1| + |-q_1 - q_2| + \dots + |-q_1 - \dots - q_k|.$$

3.3. Experimental Design

To evaluate our approach, we used the following data from registries and health surveys from the U.S.: 100,937 records about traffic accidents from the NHTSA Fatality Analysis Reporting System (FARS), 539,253 records from the American Time Use Survey (ATUS) and 1,193,504 records from the Integrated Health Interview Series (IHIS). Moreover, we analyzed a subset of a synthetic discharge dataset which is particularly hard to protect from sensitive attribute disclosure (SPD) [6]. We also included two de-facto standard datasets for benchmarking anonymization methods: 30,162 records from the 1994 U.S. Census (ADULT) and 63,441 records from the 1998 KDD competition (CUP). For a detailed specification of the datasets we refer to [7].

We anonymized the datasets with attribute generalization and record suppression to produce output datasets which fulfill t -closeness for fully ordered attributes. We varied the risk threshold t ($0.5 \geq t \geq 0.1$) to study the effect of our optimizations on different parameterizations. As a baseline, we used our original, unoptimized implementation. In the software, both pruning strategies are combined into a common implementation and we therefore present one measurement capturing both of them.

4. Results

Figure 2 shows the results of our experiments. As can be seen, our optimizations improved execution times by up to a factor of more than two. Each optimization had a positive effect in all setups while the degree of effectiveness of each optimization varied between setups. Pruning was possible in between 69% and 99% of the checks performed, but the effect on execution times varied.

The differences in the impact of optimizations on execution times can be explained by considering the distribution of sensitive attributes values in the different datasets. The impact was lower for datasets with a small number of distinct values, i.e. ADULT (7), ATUS (7) and IHIS (10), higher for datasets with more distinct sensitive values, i.e. CUP (81) and FARS (20). We measured the strongest effect for the SPD dataset, which has 101 different sensitive attribute values. When the number of sensitive attribute values is high, execution times are also higher, implying the our optimizations are more effective exactly in the cases where they are needed the most.

Figure 2. Execution times relative to the original implementation for various datasets and risk thresholds.

5. Conclusion

Due to its usability, flexibility and scalability, ARX is actively used in many areas, including commercial big data analytics platforms, medical research projects, clinical trial data sharing and for training purposes. An important reason for ARX's scalability are the many optimizations that have been integrated into the software. In prior work we have, for example, presented methods to improve the scalability of optimization algorithms for trading off risks vs. utility [8] and a versatile optimized runtime environment for anonymization algorithms [9].

In this paper, we have presented an optimization affecting a specific and important privacy model only. Our approach addresses the implementation level as well as the mathematical definition of the model implemented. Our solution utilizes high-performance data structures as well as pre-computation techniques. The model is particularly relevant in practice, as it is one of the few approaches which can be used to protect sensitive numeric data.

Abstract. The paper presents a review of current research to develop predictive models for automated detection of drug-induced repolarization disorders and shows a feasibility study for developing machine learning tools trained on massive multimodal datasets of narrative, textual and electrocardiographic records. The goal is to reduce drug-induced long QT and associated complications (Torsades-de-Pointes, sudden cardiac death), by identifying prescription patterns with pro-arrhythmic propensity using a validated electronic application for the detection of adverse drug events with data mining and natural language processing; and to compute individual-based predictive scores in order to further identify clinical conditions, concomitant diseases, or other variables that correlate with higher risk of pro-arrhythmic situations.

Keywords. Machine Learning, Clinical Decision Support System, Pharmacovigilance, Adverse Drug Events, Electrocardiography, Long QT, Torsades-de-Pointes, Repolarization Disorders, Analytic-Decision Modelling.

1. Introduction

Drug-induced ventricular arrhythmia is a major cause of iatrogenic morbidity and mortality [1], particularly in circumstances, where a wide range of psychotropic and illicit drugs are consumed (e.g. people who inject drugs, living in detention or with mental illness). Electrocardiographic (ECG) screening is a widely available method for detecting repolarization abnormalities. Long QT (LQT), defined as a QT interval duration of >470 ms for men and >480 ms for women, is the main surrogate marker for Torsades-de-Pointes (TdP), a pathognomonic, drug-induced polymorphic ventricular arrhythmia [2]. The probability to develop a TdP increases with the extent of the

¹Mina Bjelogrljic, PhD, Division of Medical Information Sciences, University Hospitals of Geneva and University of Geneva, Geneva, Switzerland. E-mail address: mina.bjelogrljic@hcuge.ch.

corrected QT interval (QTc) prolongation. Most TdP are transient and unsustained, but can degenerate to malignant ventricular fibrillation (VF) and sudden cardiac death (SCD).

Machine Learning (ML) based techniques are expected to support clinicians by allowing more accurate detection of abnormalities that would be missed using traditional diagnostic criteria (QT duration, axis, visual T-wave morphology). In the past decade, algorithms for pattern recognition and classification using learning techniques have become interesting in health applications for two main reasons; firstly, the digital information stored in Electronic Health Records (EHRs) is massively increasing [3], and there are available open databases, such as the MIT-BIH Arrhythmia Database [4]; secondly, the performance of ML algorithms have reached a point where either the task is better achieved by automatic systems, or further hidden underlying physiological phenomena can be re-addressed from a new analytical perspective. Recent research groups have tackled the problem of ECG-based heartbeat classification in order to detect arrhythmias [5]. ECG-based ML approaches include several steps after the acquisition of the ECG signals; preprocessing, segmentation, feature extraction, selection, and classification with learning algorithms [6].

2. Scope

Virtually all medications inducing LQT act by blocking the outward IKr current, which is mediated by the potassium channel encoded by the KCNH2 gene [7]. The measured QT value is further corrected according to a calculation based on heart rate (most frequently Bazett and Fridericia formulas), i.e. the QTc. Long QTc interval is a sensitive marker for TdP, but it is not specific since drug-induced QTc. More importantly, the lack of LQT specificity causes the discontinuation of valuable patients' treatment and new drug development [8]. Separate analysis of J-Tpeak and Tpeak-Tend intervals helps to identify medications which prolong the QTc interval with counterbalancing inward current block and limited risk of arrhythmias. Automated measurement methodology and algorithm for the evaluation of the early repolarization J-Tpeak and late repolarization Tpeak-Tend intervals were proposed to assess drug-induced proarrhythmia propensity, using a two-step T-wave delineation method [9]. A wide range of illicit substances and medications are associated with repolarization abnormalities. In psychiatry, risk factors for developing drug-induced TdP include chronic hepatitis C infection, HIV, electrolyte abnormalities, renal or hepatic dysfunction, pre-existing coronary heart disease, treatment with more than one QT-prolonging drug, older age, female sex, and genetic predisposition [10,11]. Abnormal electrocardiographic (ECG) recordings are reported in 27.3% of psychiatric inpatients at hospital admission and repolarization disorders were the most prevalent abnormal findings (11.8%).

3. Methodology

In the University Hospitals of Geneva (HUG), since 2017, all ECG devices (n=220) have been replaced by the same electrocardiographic devices (Philipps TC-70) and all records are automatically converted into a DICOM® [12] file (>8'000 ECGs per month performed in all care settings at HUG) and stored in the Picture Archiving Communication System (PACS) [13]. Computerized ECG health records with structured metadata in XML format are available to be extracted from the hospital DPI (Dossier

Patient Intégré) [14] secured servers for research purposes. All records can be analyzed with socio-demographic, clinical, laboratory, genetic, and drug prescription data at the individual patient level, using an agreed protocol and database structure. The latter cardiac information combined with electronic prescription systems and natural language processing (NLP), allow ECG feature extraction and drug imputability assessment, based on interactions, dose variations, and chronological relationship with drug exposition. Moreover, it stores all measurements from the recordings, meaning it includes boundary detection, epoch extraction, and characteristic measurements for each lead. In the proposed methodology (see **Figure 1**), electrographic, structured, and unstructured text data is collected and stored in a multimodal database, which will first pass a quality control, and then be used to extract and select relevant features to build models for RD prediction.

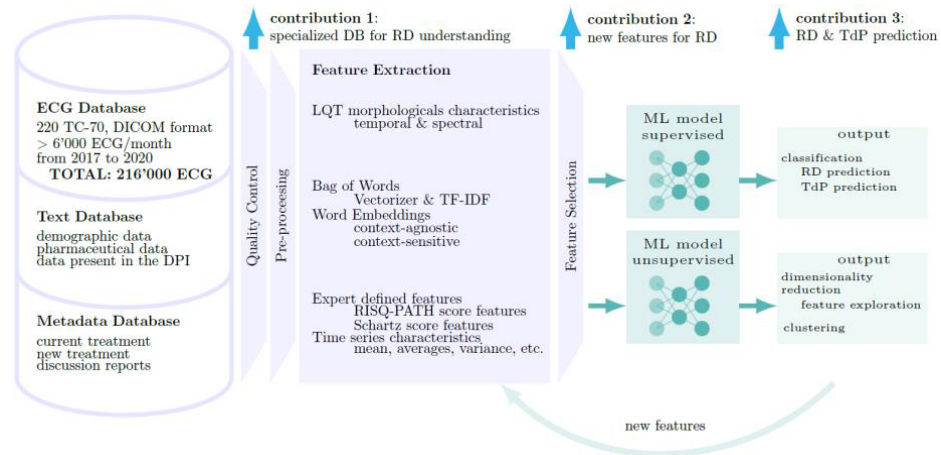

Figure 1. Research Methodology. Database (DB), Repolarization Disorders (RD), LQT (Long QT), Torsades de Pointe (TdP), Machine Learning (ML).

A feature set proposed in the literature include ECG-intervals, morphological (e.g. amplitude), Vector Cardiographs (VCG) [15], Temporal VCG (TVCG) [16], different transforms, including temporal polynomial fitting with Hermite Basis decompositions [17], and different versions of time-frequency representations, such as Discrete Wavelet Transforms (DWT) [18]. The classification, according to the resulting feature vectors is done using classifiers such as linear discriminant (LD), support vector machines (SVM) [19], Random Forests [20], and ensemble classifiers with the advantage of bagging both temporal and morphological feature-based classifiers [21]. Long-short-term memory (LSTM) networks, combined with a wavelet sequence (WS) [22], and algorithms with deep learning (DL) architectures [23] have been investigated. For inter-patient classification convolutional neural networks (CNN) and recurrent neural networks (RNN) give very promising results [24].

4. Feasibility study

There are no a priori exclusion criteria. Nonetheless, ECG of insufficient quality (not present QT measurements) or with inverted electrodes will not be included. With a

minimum 70'000 ECG recorded and saved in the hospital's database (PACS), the estimated amount of available ECG over the target period (three years) is 200'000 EC. **Figure 2** shows estimations, over a four week period, of QT density distributions depending on age and sex.

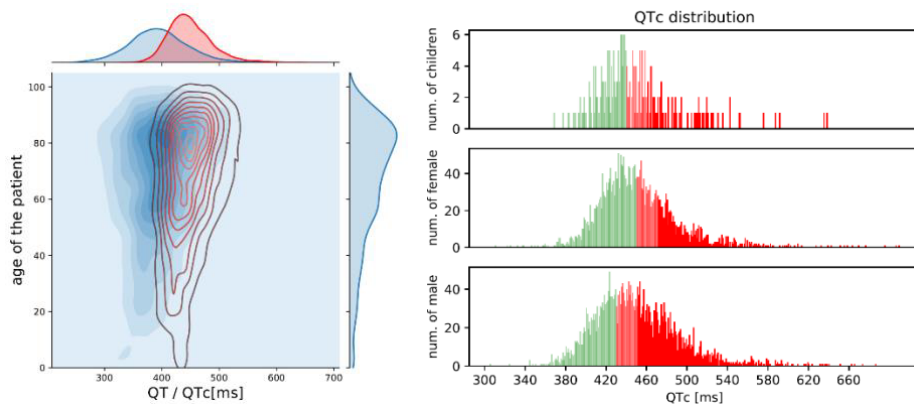

Figure 2. Left: density distributions estimation (based on a four-week period in 2019) of patient age and QT/QTc (Bazett's formula, in red) values of patients at HUG. Right: QTc (Bazett's formula) distributions over a four-week period in 2019 at HUG. For children (under the age of 15 years), women (above 15 years old, female sex), and men (above 15 years old, male sex). From green to dark red; normal, intermediate, and long QTc [ms].

5. Discussion

Approximately 30% of the inpatients are taking QT prolonging drugs, out of which 50% will have additional QT prolonging drugs [25]. In our preliminary analysis of ECG structured data (early 2019), RD prevalence and QT interval variability increased with patient age and the number of medications. The proposed research will exploit large databases to answer the central question of the influence of drugs on RD, particularly LQT and related severe complications. This question is of major importance since QT prolongation may lead to iatrogenic life-threatening arrhythmia, whose indicators could be detected to prevent consequences by instant electronic alert systems. ML-based approach could bring about innovation opportunities and new dimensions to comprehend iatrogenicity. Applied ML will influence decision-making processes (at individual and more global levels, such as health authorities), education, and training (including general practitioners, cardiologists, and medicine students). Additionally, CDSS can potentially decrease the number of misdiagnosed patients, the extra costs of non-suitable hospitalizations (40% of patients oriented to specialists for LQTS are misdiagnosed) [26], and prevent patients from severe cardiac events, such as arrhythmias or, possibly, sudden cardiac death.

Abstract. Radiology reports include various types of clinical information that are used for patient care. Reports are also expected to have secondary uses (e.g., clinical research and the development of decision support systems). For secondary use, it is necessary to extract information from the report and organize it in a structured format. Our goal is to build an application to transform radiology reports written in a free-text form into a structured format. To this end, we propose an end-to-end method that consists of three elements. First, we built a neural network model to extract clinical information from the reports. We experimented on a dataset of chest X-ray reports. Second, we transformed the extracted information into a structured format. Finally, we built a tool that enabled the transformation of terms in reports to standard forms. Through our end-to-end method, we could obtain a structured radiology dataset that was easy to access for secondary use.

Keywords. Natural Language Processing, Radiology Report, Information Extraction

1. Introduction

Radiology reports are created by radiologists to communicate with referring clinicians, and play an important role in patient care. Radiology reports are usually written in free-text format. It has been reported that the ambiguity of terminology or style in free-text can reduce the clarity of the report, causing inaccurate communication [1]. European Society of Radiology has taken the initiative in developing structured reporting to improve the quality of radiology reports [2]. They mention structured reporting also has the potential to facilitate clinical research and the development of radiological applications.

There are a lot of studies on information extraction from radiology reports [3]. Some studies examined Japanese radiology reports [4,5]. In recent years, extraction method using a deep learning has drawn much attention [6]. However, most studies have only focused on the extraction process and did not refer to the structuring process.

In this study, we propose an end-to-end approach for structuring radiology reports. Our aim is utilizing massive amounts of unstructured reports as training data for a lesion detection system [7]. Specifically, we take three steps: *extraction*, *structuring* and *normalization*. In the first step, we build a recurrent neural network-based model for entity recognition. In the second step, we organize the extracted information for storage in a database. The data is stored in a tabular database for accessibility. It is well-known that

¹ Corresponding Author, Osaka University, 1-1 Yamadaoka Suita, Osaka, Japan;
E-mail: sugimoto.kento@hp-info.med.osaka-u.ac.jp

radiology reports contain heterogeneous writing styles, including non-standard terminology and abbreviations [8]. In the third step, we transform non-standard terms in the report to a standard form.

2. Material and methods

2.1. Radiology dataset

In this study, we used chest X-ray reports from 2000 to 2017 that were stored in the radiology information system at Osaka University Hospital. The dataset consisted of 319,130 reports, most of which were written in Japanese. This study was approved by the institutional review board of Osaka University Hospital (Permission number: 17166).

2.2. Entity recognition

2.2.1. Gold Standard

We randomly sampled 5,000 reports for a gold standard dataset. A report was segmented into a single sentence and word tokenization was implemented using MeCab [9].

One non-medical expert was responsible for the annotation process. Two medical experts (a clinician and a radiological technologist) reviewed the results.

A previous study defined 5 semantic classes (*Anatomy*, *Anatomy Modifier*, *Observation*, *Observation Modifier*, and *Uncertainty*) [10]. Another defined 4 semantic classes (*Clinical Finding*, *Body Location*, *Descriptor* and *Medical Device*) [6]. With reference to previous studies, we defined 3 semantic classes: *Clinical Finding* (CF), *Body Location* (BL), and *Body Location Modifier* (BLM). CF includes terms related to observation and abnormalities in the report. BL includes terms related to the anatomical area. BLM encompasses terms that modify the BL. To differentiate the certainty of the Clinical Findings, they were split into three labels: *Clinical Finding Positive* (CFP), *Clinical Finding Suspicious* (CFS), *Clinical Finding Negative* (CFN). Figure 1 shows an example of annotation.

A part-solid nodule is seen in the left upper lung fields.
CFP BLM BL

Figure 1. annotation example

2.2.2. Neural Network Architecture

Our deep learning model is based on the architecture described by Ma and Hovy [11]. The encoder part of this model is composed of the Bidirectional Long Short Term Memory (BiLSTM) [12] layers. The character representation of each word computed by convolutional neural networks (CNNs) is concatenated with the word representation. Finally, the output of BiLSTM is fed to the CRF [13] layers to decode the label sequence.

2.3. Structuring

Entities from the report need to be transformed to tabular format records. We created simple rules using position information of the entities. In the common word order of radiology reports written in Japanese, BL appears after BLM, before CF. Based on this assumption, pairs of BLM and BL, BL and CF were created (Figure 2).

Figure 2. an example of pairs in the report

When transforming, a pair of BLM term and BL term was concatenated as one term, and a CF was divided into CF and Certainty. Multiple records were created from one sentence when BL and CF had a one-to-many (many-to-one) relationship (Figure 3).

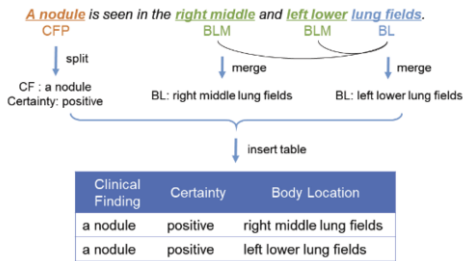

Figure 3. an example of creating records from the extracted entities.

2.4. Normalization

Each term needs to be normalized automatically. We created a concept table from scratch since there is no comprehensive radiology vocabulary in Japan. This table has 2 columns; *mention* and *concept*. Values of mention column are terms that occurred in the radiology reports, and they were collected from the outputs of our entity extraction model (As we described in 2.2.2). Value of concept column is the standard form of its mention column.

3. Results

3.1. Entity recognition

Five thousand reports were divided into 4,000 for training, 500 for development, and 500 for validation. Hyper-parameters were tuned by using a development dataset. We used

pre-trained word vectors to help the learning process. Pre-trained word vectors were obtained using Contiguous Bag of Words (CBOW) [14] from 317,130 unlabeled radiology reports. We used the RMSProp algorithm [15] with a batch size of 32. A 0.5 dropout rate was applied to avoid overfitting.

Our experimental results are shown in Table 1. Our model achieves 0.938 in the F1-score, which shows that the model can accurately extract target entities.

Table 1. Performance metrics of each semantic class

Semantic classes	Precision	Recall	F1-score	No. of entities
Body Location Modifier	0.953	0.968	0.960	4,024
Body Location	0.952	0.959	0.955	7,205
Clinical Finding Positive	0.904	0.920	0.912	7,574
Clinical Finding Suspicious	0.874	0.902	0.888	1,672
Clinical Finding Negative	0.992	0.932	0.961	2,818
Total	0.937	0.941	0.938	23,297

3.2. Structuring

We manually created 453 records from 200 reports. We evaluated the accuracy of the structuring process assuming that all entities were correctly extracted. Our structuring processor was able to correctly transform 436 records (Accuracy is 0.96).

3.3. Normalization

We created a concept table for normalization. This table was created by some medical experts (clinicians and radiological technologists). We created 21 concept terms for BL by dividing chest X-ray images. And, the concept for CF was decided by picking up frequently occurring words that were extracted as CF entity. We then combined similar concepts into one concept term. Finally, we defined 121 concept terms.

4. Discussion

In Table 1, we show the performance metrics of each semantic class. The F1-score of semantic classes exceeded 0.9, excluding CFS. The lower F1-score in CFS was related to the number of entities in the training dataset. Table 1 shows the number of entities in the CFS group was lower in comparison to other semantic classes.

As we described in 3.2, the simple rule-based method is applicable for structuring reports. This result may be due to the high similarity of the writing style of the reports.

The present study was associated with some limitations. First, some important information could not be covered in our semantic classes. For example, the size and shape of the lesions were not included, even though they are valuable for clinical research. Second, we only used an in-house dataset, which means that the performance of our method might differ if a dataset from a different hospital was used. Third, although our concept terms of BL and CF were 21 and 121, respectively, the granularity is not general and may not be appropriate for some secondary uses.

5. Conclusion

In this paper, we built an end-to-end method for transforming unstructured radiology reports into a structured format. We combined machine learning for entity recognition with a rule-based method for structuring and normalization to pursue a better approach. While our method leaves room for improvement of versatility, the present study shows the way to facilitate secondary use of radiology reports.

Abstract. This paper presents five document retrieval systems for a small (few thousands) and domain specific corpora (weekly peer-reviewed medical journals published in French) as well as an evaluation methodology to quantify the models performance. The proposed methodology does not rely on external annotations and therefore can be used as an ad hoc evaluation procedure for most document retrieval tasks. Statistical models and vector space models are empirically compared on a synthetic document retrieval task. For our dataset size and specificities the statistical approaches consistently performed better than its vector space counterparts.

Keywords. Medical Information Retrieval, Document Retrieval, Natural Language Processing, Word Embedding.

1. Introduction

The field of Information Retrieval (IR) is a well-studied and yet still critical field of research. In the last few decades, additional effort has been made in the biomedical domain with the digitalization of medical data and the multiplication of biomedical scientific literature [1,2]. The goal of the present paper is to give a clear methodology in evaluating several IR systems on small (few thousands) and domain specific corpora (medical literature in French). For a specific query, document ranking is determined by a numerical score assigned by the IR system [3]. On the one side, early IR systems in the early 60's were based on Boolean and statistical approaches [4]. In term-based approaches documents are represented by a predefined arbitrary feature with no encoded semantic information (words are represented by an index in a vocabulary). On the other side, vector space (VS) models represent documents as a composition of vector representation of terms [5]. In VS each word is encode as a vector in a high dimensional space allowing to encode semantic information. Independently of the representation

¹ Authors contributed equally to this work, Division of Medical Information Sciences, University Hospitals of Geneva and University of Geneva, Geneva, Switzerland E-mail: Firstname.Lastname@hcuge.ch

used, most Document Retrieval systems compute a ranking between a query and all the documents in the corpus [3]. The documents with the highest score (rank) are considered most relevant and are returned [6,7]. Statistical models (*Boolean* and *Weighted*), vector space models (*Word2Vec-Mean* and *Word2Vec-Weighted*, *Word2Vec-Max*), are compared on a dataset consisting of 4,201 articles of weekly peer-reviewed medical journals published in French. All models are evaluated empirically on the same document retrieval task.

2. Data/corpus

The source of the dataset is the *Revue Medical Suisse* (RMS). The dataset consists of 4,201 articles of weekly peer-reviewed medical journals published in French in XML format spanning from years 2014 to 2019. Sections of the document such as the abstract, title, body, conclusion and references can be distinguished by specific XML tags. In order to evaluate the models performance we kept articles for which title, abstract and body were available and in French, which resulted into 1,401 documents. All models benefited from the same preprocessing steps. The first step consists into the extraction of the documents from the XML format to plain text. Then, each document is converted into lemmatized tokens (49,573 unique terms). Lemmatization is done by *Spacy*'s pre-trained statistical models for French [8]. Stopwords are removed (they do not add any semantic information), verbs are removed (add small semantic information), and word that occurs less than 2 were removed (to filter out mostly misspellings and extremely rare terms). Following this procedure, approximately 42% of words were filtered out, leaving a vocabulary size of 28,791 terms.

3. Methodology

We investigate different methodologies to rank documents according to a query. The proposed models fall in one of the two following categories: Term-based or VS models. The term-based models evaluated (*Boolean* and *Weighted* models) represents words as an index in a reference vocabulary while VS models represent words as vector in a high dimensional space [5], which encode semantic properties of the word. The evaluated VS models (*Word2Vec-Mean*, *Word2Vec-Weighted*, *Word2Vec-Max*) represent each term as a m -dimensional vector v using the well-known *Word2Vec* algorithm [5], where m is a user chosen parameter (called embedding size).

3.1. Term-based Models

In the *Boolean model*, for a vocabulary size of n words, the model encodes a text as an n -dimensional vector containing a '1' for each word present in the text and '0' otherwise. In order to evaluate the similarity between a query q and a document d the model first normalizes the two vectors: $\bar{q} = \frac{q}{\sum_i q_i}$, $\bar{d} = \frac{d}{\sum_i d_i}$, and then compute the cosine similarity between \bar{q} and \bar{d} , where the cosine similarity between two vectors a and b is defined as follow:

$$\text{sim}(a, b) = \frac{\sum_i a_i b_i}{\sqrt{\sum_i a_i^2 \cdot \sum_i b_i^2}} \quad (1)$$

The main drawback of the *Boolean model* is that it gives the same importance to all the words in a document. To include the word importance, the *Weighted model* uses the TF-IDF (for term frequency - inverse document frequency) metric that weight the importance of a term in a document. More formally TF-IDF will compute the weight of a term as follow:

$$\begin{aligned} \tilde{w}_d(t) &= \text{freq}_d(t) * (\log \frac{D+1}{d(t)+1} + 1), \\ w_d(t) &= \frac{\tilde{w}_d(t)}{\sum_{t'} \tilde{w}_d(t')}, \text{ with } \tilde{w}_d(t) = \text{freq}_d(t) * (\log \frac{D+1}{d(t)+1} + 1) \end{aligned} \quad (2)$$

where $\text{freq}_d(t)$ denotes the number of times the term t appears in the document d , i.e the term frequency and $d(t)$ denotes the number of documents that contain the term t , i.e. the document frequency. Query and documents are compared using cosine similarity (see eq. 1) [9].

3.2. Vector Space Models

For all VS models word representation was computed with *Word2Vec* algorithm, with an embedding size of 32, a context window size of 7, and 64 negative samples.

In *Word2Vec-Mean model*, documents are represented as the mean of their word vectors:

$d_j = \frac{1}{|d_j|} \sum_{i \in d_j} v_i$, where v_i is the m -dimensional vector representing word i . Queries

are represented with the same methodology. For a given query, the relevance of a document is computed with the cosine similarity (see eq. 1). The main drawback of the previous method is that it assigns the same weight to all words of the document. An alternative (*Word2Vec-Weighted model*) is to use the TF-IDF weights (see eq. 2), and

represent a document as follow: $d_j = \frac{1}{\sum_i w_{d_j(i)}} \sum_{i \in d_j} w_{d_j(i)} v_i$

When representing a document with the above methods, the mean can involve a potentially large number of vector (several hundreds), hence drowning the information in the mass. The *Word2Vec-Max model* solves this problem by focusing on the few words that are the most relevant regarding the query. For each term of the query q the algorithm find the closest term (w.r.t. the cosine similarity, see eq. 1) in the document and average them to compute the final similarity score: $\sum_{q_i \in q} \max_{d_j \in d} (\text{sim}(q_i, d_j))$.

4. Experiments

The dataset for testing consists of 1400 medical articles from RMS Journal. In order to evaluate the above information retrieval systems we used an article's title as a query. The precision of the model is then evaluated, by looking if the corresponding article appears in the top-N most relevant documents (N=1, 5, 10). Performance of some methods might fluctuate depending on the length of the documents composing the corpus, therefore, experiments were conducted on 3 different corpora:

- Corpus A, contains only the abstracts of the articles (25 to 184 words);

- Corpus B, contains only the body of the articles (431 to 8,839 words);
- Corpus A+B, contains both the abstract and the body of the articles.

Titles, used as queries, have from 1 to 29 words (mean=9.7 words) and the total number of words is the whole corpus is 1,853,939 (in titles + abstracts + bodies).

Figure 1. Performance according to query length. From left to right, it shows the top1, top5, and top10 performance. Models are color coded, and the size of the marker is proportional to the support size (i.e. number of queries).

For all the documents, all models, and the three different corpuses, the top1, top5, and top10 performances are shown in Table 1. The best performance for almost all sub-tasks is obtained by the *Weighted model*. In order to quantify the impact of the query length, Figure 1 shows the performance of each model according to the query length. The dominance of the *Weighted model* (in dark blue) is confirmed by this new perspective. The performance is the ratio between the number of queries where the correct document was in a specific ranking (i.e. top1, top5, top10) and the total number of queries. We achieve up to 94.5% of retrieval with top10 metric for 7 concept long queries.

Table 1. Shows the top1/top5/top10 performance of the five models on 1400 different queries

Method	Abstracts only	Bodies only	Abstracts + bodies
Boolean	801/1071/1138	564/963/1084	595/979/1092
Weighted	876/ 1186/1240	838 /1195/ 1276	861/1218/1295
Word2Vec- Mean	422/785/920	405/749/900	421/766/915
Word2Vec- Weighted	486/804/949	458/812/941	474/831/955
Word2Vec-Max	882 /1135/1192	572/982/1098	598/1004/1114

5. Discussion

First, it is important to note that the task is prone to advantage index-based methods since it is very likely that words that appear in the query (title) will occur in the target article. Hence, it might explain the very good results obtain by index based methods. Secondly

it seems that VS space models that compute document representation using all terms in the documents fail to provide a good representation, as suggested by the poor results obtained by *Word2Vec-Mean* and *Word2Vec-Weighted models*. This is also confirmed by the performance gain seen with *Word2Vec-Max* (which use less terms to represent documents).

6. Conclusion

This paper shows and evaluates how various document representations can impact the performance of a Document Retrieval system. The presented models are separated into two groups: term based and vector space models. In total we described and evaluated 5 models: *Boolean*, *Weighted*, *Word2Vec-Mean*, *Word2Vec-Weighted*, *Word2Vec-Max models*. The relevance of a document with respect to a query was computed using the cosine similarity between their appropriate representations. By varying the query length we see how the models perform in retrieving the top 1/5/10 documents.

Future work should focus on: (i) evaluating the presented methods against a much larger corpus (rather than only 1400 articles); (ii) investigating more in depth document representation (the *Word2Vec Max* use only a small subset of words, as many as the query length, to represent a document, this information loss impact the severely the document representation); (iii) efficient implementation of those systems to scale to larger database. The methodology proposed in this paper can be used as an ad hoc evaluation procedure for most document retrieval tasks in small and medium size text databases, in order to adopt the most effective IR strategy.

Abstract. The aim of our validation study was to assess the quality of hospital data for perinatal algorithms on a national level. In each hospital, we selected 150 discharge abstracts of delivery (after 22 weeks of gestation), in 2014, and their corresponding medical records. Overall, 23 hospitals were included and 3,246 discharge abstracts were studied.

This first national validation study of several case-finding algorithms using various perinatal variables suggests that the French national hospital discharge abstracts database is an appropriate data source for epidemiological studies.

Keywords: hospital data, perinatal indicators, validation study.

1. Introduction

Administrative data, such as hospital or care consumption, that are collected primarily for reimbursement, contain several clinical diagnoses and procedures, which can be used to provide epidemiologic information (1). In France, 99.6% of the 800,000 annual births in France take place in hospitals (2). This renders the French hospital database particularly interesting for the investigation of perinatal. Nonetheless, the researchers using the medico-administrative databases are required to evaluate data quality via a validation study (3–7). In validation studies of case-finding algorithms, validity indices are used to assess data quality by comparing an algorithm in the simpler and easier-to-use data set versus a more elaborate, robust and reliable data set that is considered to be a “gold standard”. Furthermore, other validity indices are used to aid the selection of the best algorithms. In contrast to the less frequently conducted national surveys, the use of routinely collected health data in hospitals saves time and money when identifying infrequent and unfavorable delivery outcomes and improves health surveillance of women and their offspring (1).

The aim of our validation study was to assess the hospital data quality for perinatal algorithms on a national level.

2. Methods

The principle of this transversal multicenter study was to compare discharge abstract data entered into the French hospital database with the corresponding data from medical records, where we considered the latter to be the gold standard.

2.1. Population

Fifty health hospitals with a maternity unit were randomly selected in metropolitan France (other than Paris and Paris region), irrespective of the level of the unit. We developed a software program to randomly select 150 perinatal discharge abstracts per hospital (≥ 22 weeks of gestation) in 2014, from all discharge abstracts that contained a Z37 code and/or a delivery procedure. The same investigator collected data in each hospital from hospital paper-based or electronic medical records of pregnancy (prenatal care, the delivery and the post-delivery stay, and a discharge letter). Then, a comparison between data from medical records and data from discharge abstracts was made.

2.2 Statistical analysis

We explored several algorithms, including different combinations of codes in discharge abstracts from delivery stay, pregnancy stay, or hospitalization over the past 2 years before delivery. To evaluate the quality of the hospital database of discharge abstracts versus the hospital medical records (our gold standard), two validity indices the positive predictive value (PPV) and the sensitivity were calculated for dichotomous data. Continuous data were assessed by the concordance rate as the validity index. The rates of false negatives (FN) and false positives (FP) were also calculated in order to select the best algorithms with regards to the likelihood ratio (balancing specificity and sensitivity). This study was approved by the French National Committee for Data Protection (registration number 9132091). To meet the requirement of the data protection agency, the family names and first names were removed, the date of birth was replaced by the age at delivery, and the dates of admission and discharge were replaced by the length of stay.

3. Results

Twenty-two hospitals were finally included. Among them, 5 maternity units had less than 1,000 deliveries, 4 units had between 1,000 and 2,000 deliveries, 5 units had between 2,000 and 3,000 deliveries and 8 maternity units had more than 3,000 deliveries. Overall, 3,246 discharge abstracts were compared with their corresponding medical records.

3.1. Maternal indicators

The concordance rate of maternal age at delivery was 94.8%, with a 95% confidence interval (CI) [93.8-95.4]. The maternal characteristics and several types of morbidity are presented in Table 1.

The pregnancy-related disorders are presented in Table 1. The concordance rate of gestational age at delivery was 91.8% [90.9-92.7]. Rounding up or down to the nearest whole number of WG (< 1 week), the concordance rate increased to 98.3%.

The indicators of delivery are presented in Table 1. Regardless of the algorithm explored, the PPV for vaginal delivery was over 99%. In order to select severe postpartum hemorrhage, we explored advanced interventional procedures which indicated a second-line therapy (arterial embolization, uterine or hypogastric artery ligation, hemostasis hysterectomy).

The concordance rate between the vital status and the diagnosis codes for stillbirth from newborn discharge abstracts was 95.4% [94.7-96.1] for singleton pregnancy. For multiple pregnancies, the rate was 99.7% for the first- or the second-born child, and 100% for the third-born child.

3.2. Newborn indicators

The concordance rate of newborn weight was 91.3% [90.3-92.3] in singleton pregnancy. The rate was 79.1% [70.5-87.5] for first- and second-born in cases of multiple pregnancies. As regards the first-born child, the median gap between the newborn weight mentioned in the medical record and the weight specified in the discharge abstract was 100g.

4. Discussion

4.1. Main findings

Our study has shown that the French hospital perinatal discharge abstracts database, when compared with hospital medical records (our gold standard), regarding parturient women, pregnancy and delivery is highly accurate. Gestational diabetes had a higher metrological quality than the other types of diabetes. Several algorithms were studied using the data of hospital stay during pregnancy or during delivery. They did not improve the identification of women who had gestational diabetes. The algorithm including one of two gestational diabetes diagnosis codes (O24.4, O24.9) from the hospital stay of delivery remains the most performant. The algorithms for stillbirths and termination of pregnancy for medical reasons were found to be accurate.

4.2. Strengths and limitations

Our national study included maternity units of all types and all volumes of deliveries. Moreover, in France almost all deliveries occur in a hospital. We explored a large number of perinatal indicators: 70 items were collected for each hospital stay by a single technician specialized in clinical studies. Some limitations also have to be acknowledged. The data collection was performed by a technician, perfectly trained, but not by a health professional. The maternity units included in our study were geographically not distributed uniformly throughout the French territory. It is very important to assess the data quality in case-finding algorithms so that the design of an envisaged study can be adjusted according to the quality of data (4,8). Our results suggest that it seems possible and worthwhile to conduct studies on women with a history of gestational diabetes. The use of a complementary French database for ambulatory care (treatment, biology) has been suggested as a means to identify women with gestational diabetes or pre-existing diabetes, but it is necessary to assess the data

quality of this algorithm (9,10). The quality of the French hospital database for stillbirth and medically indicated abortion was high. Thus, it seems possible to use these two indicators not only for descriptive studies, but also for longitudinal studies.

Conclusion

This first national validation study of a large set of perinatal algorithms has shown that French hospital database is an appropriate data source for subsequent epidemiological studies. The choice of the algorithm may vary, depending on the aim of the study. Nevertheless, the data quality of the algorithms should be taken into account to define the design of the study.

Abstract. Managers, physicians and researchers need to study patient's path for purposes of management, quality of care and research. We present the proof of concept of the use of a flow diagram, the Sankey diagram, to visualize the trajectory of a population that experienced an event. This representation was tested with two case studies in populations from the anesthesia data warehouse of Lille University Hospital. For the 551 patients undergoing a pancreaticoduodenectomy, Sankey diagram helped us identify atypical care paths of patient being transferred too late in an intensive care unit. For 473953 patients who have had anesthesia procedure, Sankey diagram highlighted that mortality and re-operation rates increase with the number of operations. This preliminary work has been well received by end-users and allowed managers, physicians and researchers to visualize the paths of patients and to provide visualization support for research questions. This work will be followed by generalization.

Keywords. Data Visualization, Data Reuse, Patient Path, Sankey Diagram

1. Introduction

To display complex information in a most effective way, graphical representations are more appropriate than tables and figures [1, 2]. In healthcare facilities, to have access to visual representations of patients' path would be of great value for assessing quality of care (e.g. to detect atypical care paths) and for management purpose [3]. From a research perspective, studying patient flows may generate hypotheses about patient care that can be assessed later with classical biostatistics methods.

Designing and providing clear and efficient visualization of patients' paths faces several issues:

- Hospital Information Systems (HIS) generate a huge amount of data and the patient path is documented by many variables (admission and discharges modes, type of units, succession of interventions and re-interventions, medical acts, diagnostics, etc). This makes it difficult to extract relevant information;

¹ Corresponding Author, Antoine Lamer, 2 avenue Oscar Lambret, 59037 Lille cedex, France; E-mail: antoine.lamer@chru-lille.fr.

- Patients' stays differ in complexity and may represent a large number of patterns (e.g. one patient went through two care units and underwent one operation while another went through 6 units and underwent two operations).

Several kinds of diagrams are commonly used to represent flows. From a practical point of view, a flow is a succession of steps, each one defined by an initial state, a final state, and a quantity. From a graphical point of view, it is represented by links carrying information about quantity from start nodes to end nodes. Table 1 compares 8 types of flows diagrams [4]. Most of these representations enable to visualize only one step of a process. On the contrary, the Sankey diagram enables to represent several steps along with the information about flows' volumes, and to manage the complexity of the patient paths.

This work aims to assess whether the Sankey diagram is feasible to represent patient paths, in a way that would be readable and understandable by clinicians. With this goal in mind, two cases were used: (i) paths of patients with the pancreaticoduodenectomy and (ii) association between re-operation and mortality.

Table 1. Comparison of flow diagrams

Flow diagram	Advantage	Limit
Network Diagram highlights connections between nodes at a given step.	The connections may be directed and weighted.	It addresses only one step of the whole path.
Chord Diagram is similar to network diagram, except that nodes are represented in a circle.	The same as Network diagram.	It addresses only one step of the whole path and presents reading difficulties.
Dendrogram is a tree displaying paths from the first to last step and considering the intermediate states.	It displays successive steps of the path with detail about the count.	It displays as many final nodes as paths, which overwhelms the diagram.
Sunburst Diagram is a circular representation of the dendrogram: the inner circle represents the first step of the process and each additional layer represents a new step.	It displays successive steps of the path with detail about the count, and aggregate links at every steps.	The number of steps must be limited. At each step, patients with the same criteria are displayed on different parts of the circle, which makes the reading harder.
Sankey Diagram displays flows between successive steps through arrows whose thickness is proportional to flow quantity.	It displays successive steps of the path with detail about the count.	For clarity sake, the number of steps must be limited.
In the Agenda Diagram , each row represents an individual and each cell represents a time unit.	It displays every detail for each patient.	It does not synthesize information on the whole population.
Connection Map is connecting locations placed on a map.	It highlights flows between distant places.	It represents only one step of the path and does not consider the volume of flows and the temporal sequence.
Funnel Chart represents the successive proportions of a given population that meet given criteria.	Readability.	Only one final sub-population.

2. Materiel and methods

We worked on two different cases to illustrate the design of the Sankey diagram used to represent patient paths. Each case aimed to answer a question: (i) in the digestive surgery department, what is the patient volume in each care unit after surgical operation for pancreaticoduodenectomy and what are the atypical patient paths? (ii) how mortality is related to the number of surgical operations during an hospital stay?

To design the Sankey diagrams and representing answers to those questions, we used data from the anesthesia data warehouse of Lille University Hospital. This data warehouse stores and organizes data about surgery and anesthesia procedures (drugs, vital signs, steps of surgery) with administrative data (hospital stay characteristics, medical unit, entry and discharge modes, medical and surgical acts, diagnoses) [5,6].

The Sankey diagrams were designed following three stages. The first stage is crucial and consists in determining information needed to answer the question. The information are summarized in Table 2.

Table 2. Aggregated data to upload in the graphical library

Source node	Case study 1	Case study 2
Population	Patients who undergo a duodenopancreatectomy (HNFA007 code)	Patients who undergo an operation
Event under scrutiny	Admission to unplanned critical care unit after operation	Death and re-operation rates
Steps of the path	Successive medical units after operation	Discharge status after each operation

The second stage consists in aggregating the data and compute the count of patients in each step between two successive states of the path. For each link, we had to provide a source node, a target node and the quantity between the two nodes. Finally, these aggregated data are loaded into graphical libraries (D3.js and D3sankey [7]).

The resulting Sankey diagrams were presented to clinicians to get their feedback on the readability, the understandability of this visual representation and its impact.

3. Results

3.1 Case study 1 : Patient flow for pancreaticoduodenectomy

Operations of pancreaticoduodenectomy were selected based on the code HNFA007 of the French medical act classification (CCAM, Classification Commune des Actes Médicaux). For operations between 2010 and 2018, 551 patients were included. We selected two significant states of the hospital stay for pancreaticoduodenectomy: the post-operative unit and the last unit before discharge from the hospital. These two states were characterized with the type of unit (conventional, continuous care or intensive care unit) and final discharge status (mortality) was reported. The Figure 2 is the Sankey representation for this population.

Two managers and two physicians examined the Sankey diagram. They were able to describe patient flows in each unit after operation. Moreover, physicians highlighted atypical paths: some patients were transferred from conventional care unit to critical care after operation, and some patient died even though they did not go through critical care beforehand. They reported that this Sankey diagram was intuitive to read, more understandable than a table but that they needed contextual information when the graph is accessed for the first time. Physicians will now investigate why these patients were not treated earlier in an appropriate care unit.

Figure 1. Patient flow for pancreaticoduodenectomy

3.2 Case study 2: Mortality rates after re-operation

Between 2010 and 2018, 473953 patients underwent operation. For each patient, we computed the number of operations, and final discharge status (death). In order to get the most out of the diagram, two key points were relevant. First, we had to define a maximum number of operations to be covered. Secondly, we had to display results in percentages to compare modalities with small numbers (3rd and 4th surgical procedures) with larger modalities (1st and 2nd surgical procedures). With the Sankey diagram in Figure 2, we can see that mortality and re-operation rates increase with the number of operations performed during the same hospital stay. This diagram has been shown to 2 managers and 2 physicians, and they all agreed on the intuitiveness of the information displayed. They only asked for contextual information to know the source of the data. According to them, this result will be the starting point of research program about how going through multiple operations could impact mortality rates.

Figure 2. Sankey diagram representing the mortality and re-operation rates according to the number of operations during a hospital stay

4. Discussion

In this paper, we offer a way of visualizing patients' path with the Sankey diagram. This representation allowed managers, physicians and researchers to visualize the paths of patients, to detect atypical patient flows between units and to provide visualization support for research questions. We will now investigate which signals in operating room and post-anesthesia care unit could be used to detect patients prone to complications and refer them to an intensive care unit as soon as possible.

Usually, end-users are provided with data in a table format, on a case-by-case basis, or for a single step of the patient path. With the Sankey diagram, the benefits reported by users are that this representation is easily understandable, gives a useful overview of patient path and offers the opportunity to identify atypical paths that they may not have seen otherwise. It could also be used as a way to validate their hypotheses and further investigate.

However, the implementation of such diagrams might be challenging as patient paths have more than two steps and are complex. Thus, the data aggregation must be adapted to the specific issue to deal with. Moreover, the steps displayed must be selected to highlight important facts and avoid overload of information.

A limitation of the Sankey diagram, with its current implementation, is that it is not possible to follow an individual path from the first to the last node. The next step is to improve the current Sankey representation by adding a traceable multi-level feature. This would represent a more precise way to highlight a specific path.

Another perspective would be to offer an online Sankey visualisation tool, in which the users would select the targeted population (e.g. a surgical act) and predefined steps (e.g. surgical complication) to have a display of the corresponding patients' path.

Abstract. The increasing demand for territorial services requires the improvement of the coordination and cooperation among stakeholders in planning and delivery of integrated health and social services. In this scenario, to improve the communication among stakeholders there is a need of a formal conceptual model that facilitates the interoperability between organizations and professionals. This paper presents the methodology adopted by a UNINFO working group established in Italy to extend the ContSys standard with social care concepts to integrate health and social care contexts in a continuity of care perspective. An example of this extension is also provided considering the definition of patient's care plans.

Keywords. Continuity of Care, Integrated Care, ContSys standard, Semantic interoperability, Health and social care services

1. Introduction

In recent decades there has been a change in the provision of health services privileging home care over hospitalization [1]. This is considered a sustainable approach that not only leads to significant cost savings, but also allows optimal results to be achieved in providing high-quality health services as well as offering an improvement in the individual's quality of life [2]. Furthermore, the rapid development of medical and non-medical technologies facilitates the provision of home care services, supports care coordination among professionals as well as allows remote patient monitoring [3]. However, a critical aspect considering the provision of services both in the home environment and in the community is their fragmentation that leads to scarce outcomes and wasted resources [4]. Thus, in this perspective, an important target to be accomplished is the improvement of the coordination and cooperation among stakeholders considering the different needs of the target population both between primary and secondary care (vertical perspective) and between health and social care settings (horizontal perspective). In this scenario, one of the first issues to be tackled to

¹ Fabrizio Pecoraro, Institute for Research on Population and Social Policies, Via Palestro, 32 – 00185 – Rome, Italy; E-mail: f.pecoraro@irpps.cnr.it.

improve the communication among stakeholders is the definition of a formal conceptual model that defines the concepts needed to facilitate the interoperability between organizations and professionals. Among the standards developed in healthcare ContSys (A system of concepts for the continuity of care, formally ISO 13940 [5]) represents a suitable starting point to accomplish our task. It is focused on semantic interoperability that is one of the major requirements to achieve the continuity of care. ContSys has the advantage of considering continuity as the integration of different health services provided by formal and informal carers belonging to different types of organizations such as primary care, hospital, territorial, community. Moreover, this standard provides a comprehensive conceptual framework to describe generic concepts that represent both the content and context of the health services with well-defined relationships among a large set of classes that describe in details the healthcare process [6]. However, even if ContSys states that also social care has the objective to influence, restore and maintain health, this standard only indirectly include social care within the wider spectrum of health concepts. This paper starts from a previous work [7,8] where we introduced a preliminary idea of an integrated model that collates healthcare, social care and assistive domotics elements to define the conceptual model of an interoperable open platform, called H@H, that organizes the provision of a set of home care services. The resulting conceptual model was confined on the portion of the ContSys standard fitting with the purposes of the H@H project. Starting from the results achieved in these papers a working group was launched at the UNINFO, the branch of the Italian National Unification (UNI) Standardization body that tackles the Information and Communications Technology (ICT) activities, to put in practice the idea of extending the ContSys standard as a whole.

The aim of this paper is to describe the methodology adopted by the working group to extend the ContSys standard with social care concepts to establish an overall schema that models the integration between care professionals in a continuity of care perspective. The steps of the methodology are described in Section 2, while Section 3 reports the application of these steps to define patient's care plans.

2. Methodology

The extension of the ContSys model was performed on the basis of the following steps.

Step 1. Analysis of the ContSys concepts in the light of the social context. Given the structure of the ContSys standard and the relevant technical document, each clause of the conceptual schema was analysed taking into account its concepts as well as the related classes. Each concept was analysed considering its definition, the relationships with the relevant classes (type, name and cardinality) as well as notes and examples. On the basis of this analysis the working group determined whether the concept can be:

- a. *Included as it is.* This category refers to universal concepts that already include in their definition, notes and examples references to social care. Examples are: subject of care, health resources such as funds;
- b. *Included but extending the vocabulary with social references.* These concepts need to be revised in terms of notes and/or examples or slightly modified in their definition. Examples are: health matter, contact.
- c. *Included identifying a new specific concept.* These concepts explicitly describe the clinical process but have a counterpart within the social context and can be integrated within the model. This required the creation of a new concept

targeted to the social model. This can imply the redefinition or the introduction of new relationships. Examples are: clinical process, health issue.

- d. *Excluded* given that these concepts describe the clinical side of care and are not needed for the social context, such as adverse event.

Step 2. Definition of the combined model. Once all concepts were analysed a conceptual schema describing the social side of care and its relationships with the clinical side of care was defined. The resulting model was composed of three main sections. The first two sections describe separately the healthcare and the social care contexts, while the third one concerns concepts that are shared between the two above mentioned sections. Moreover, additional associations are determined to capture the relationships between the health and the social parts of the schema.

Step 3. Definition of the integrated model. Once the model that combines both the healthcare and the social care perspectives is defined, the final step of the methodology concerned the identification and modelling of the part of the model where services are delivered in a professional collaboration and integration perspective. This is mainly applied considering the assessment and planning activities that can be carried out by a multidisciplinary team of specialists belonging to health and social care organizations.

The analysis carried out during each step of the methodology can facilitate the refinement of the models defined in the previous steps in an iterative approach. In the following paragraph an example of the application of the methodology is described analysing the healthcare planning clause of the ContSys standard [5].

3. Results

Figure 1 shows the combined model (see step 2 of the methodology described in the previous paragraph).

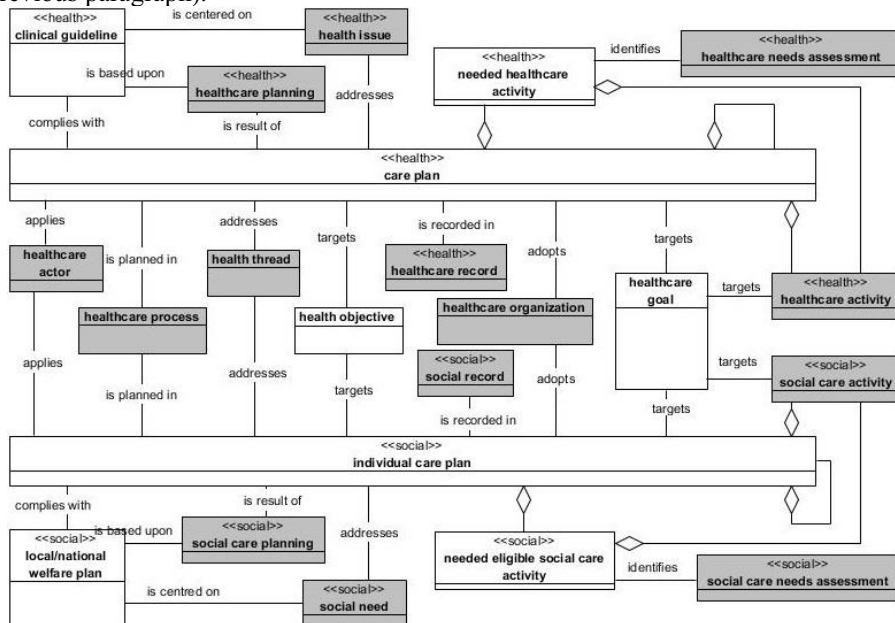

Figure 1. Combined model highlighting classes defined in the ContSys Healthcare Planning clause (white) and those defined in other clauses (grey). <<Stereotype>> highlights health and social care classes.

The core class of the social section is the Individual Care Plan (ICP) (also known as Piano Assistenziale Individuale (PAI) in Italy) that is focused on one or more social needs. It is composed of a set of needed social care activities and a set of planned or delivered social care activities. The plan is stored in a social record that concerns a specific subject of care. A similar description can be seen considering the healthcare section of the schema, while in the common section a set of goals and objectives that are in common in both contexts are associated with health and social care plans. Similarly, the health thread, that is in common with the two sections of the schema, is adopted to associate both health issues and social needs of the relevant subject of care. As introduced in the methodology, the integration of health and social care contexts does not only imply that a subject of care accesses to these services separately, but also to a set of activities that are carried out by a multidisciplinary team in an integrated approach in a continuity of care perspective. This may occur especially during the planning activities. In case of an integrated context, a set of activities may be provided by a team on the basis of a collaborative and continuity of care approach. For this reason, the planning clause of the model was additionally extended by including the integrated plan of care concept. It is important to stress that an integrated plan cannot be considered only as a composition of health and social care plans because it has to:

- Incorporate a set of needed and provided *health, social care and integrated care activities*;
- Target a set of *objectives and goals*, that are shared between contexts;
- Be stored in an *integrated care record*;
- Be applied by different *actors* involved in the health and social care sectors;
- Plan a *healthcare process* that describes both health and social care contexts;
- Address a *health thread* that links both *health issues* and *social needs*;
- Be planned during a set of integrated activities involving both health and social care professionals (*integrated planning*);

On the basis of these features an additional model that describes the healthcare integrated planning clause is defined and shown in Figure 2.

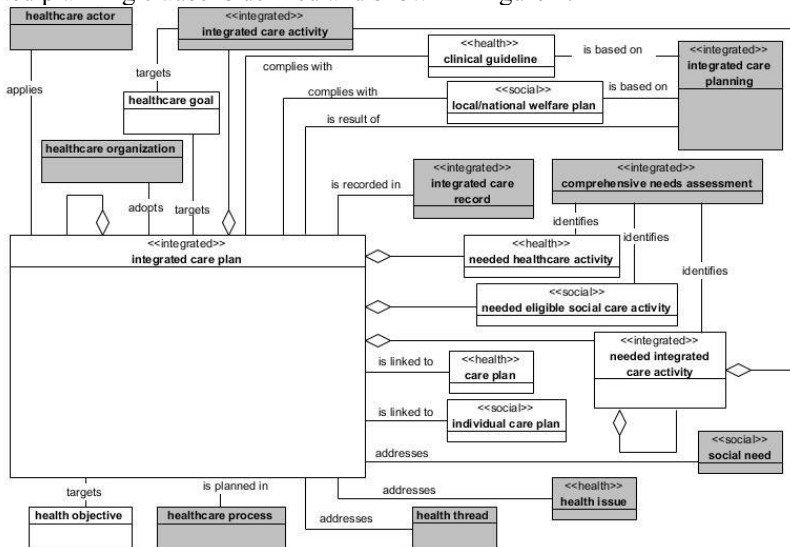

Figure 2. Integrated model highlighting classes defined in the ContSys Planning clause (white) and those defined in other clauses (grey). <<Stereotype>> highlights health, social and integrated care classes.

4. Discussion

This paper describes the methodology proposed by the UNINFO Working Group in Italy to extend the ContSys standard to social concepts. It provides an example of the definition of the individual care plan established in the social context to track the activities (both needed and provided) related to one or more social needs of a specific subject of care. Moreover, as different services can be planned and provided by a multidisciplinary team composed of both health and social care professionals, an integrated plan is envisioned. The adoption of the integrated model could facilitate the interoperability between systems as well as the coordination and cooperation activities of the different actors involved in the provision of services in a comprehensive continuity of care process.

At the moment the UNINFO team has analyzed the different concepts of the standard identifying an extension of the model as well as capturing the part of the model where an integrated view of the care can be modelled. Moreover, thanks to the interdisciplinary composition of the team, that also comprises researchers and professionals belonging to social care, a set of scenarios have been collected to capture and assess the completeness of the extended model. The debate set up within the UNINFO group can be a starting point to provide suggestions to the established ISO working group for the revision of the ContSys standard.

Abstract. Introduction: Computable phenotypes are gaining importance as structured and reproducible method of using electronic health data to identify people with certain clinical conditions. A formal standard is not available for defining and formally representing phenotyping algorithms. In this paper, we have tried to build a formal representation of such phenotyping algorithm. **Methods:** We built EN 13606 EHR standard for building clinical archetypes to represent the computable phenotyping algorithm for 'diagnosis of cardiac failure'. As part of this work, we created a set of new clinical archetypes for defining 'cardiac failure diagnosis'. The EN13606 editor called Object Dictionary Client was used which was in-house developed by University College London. We evaluated the ability of EN 13606 to provide clinical archetypes to define EHR phenotyping algorithms using the predefined desiderata for the purpose [Mo et al]. **Results:** EN 13606 archetypes could represent phenotype components grouped and nested based on their logical meaning. It was possible to build the EHR phenotyping algorithm with the clinical elements and their interrelationships along with hierarchical structure and temporal criteria. But the specific mathematical calculation and temporal relations involved in the algorithm was difficult to incorporate. These will need to be coded and integrated within the clinical information system. These archetypes can be mapped for comparison with the openEHR models. Binding to external clinical terminology is fully supported. However, it does not satisfy all the desiderata defined by Mo et al. A possible way could be an approach using phenotype ontologies and its architectural representation integrated with ISO interoperability. **Conclusion:** The EN13606 archetypes can be used to define the phenotype algorithm that basically identifies patients by a set of clinical characteristics in their records. Phenotype representations defined in EN 13606 do not satisfy all the desiderata proposed by Mo et al. and thus currently has a limited ability to define the computable phenotyping algorithms. Further work is required to make the EN13606 standard to fully support the objective.

Keywords. computable phenotypes, EN13606, archetypes, EHRs, algorithms.

1. Introduction

A computable phenotype refers to a clinical condition or characteristic that can be determined with a computerised query to an Electronic Health Record (EHR) system or clinical data repository using a defined set of data elements and logical expressions (<https://rethinkingclinicaltrials.org/resources/ehr-phenotyping/>). Standardised

computable phenotypes can promote efficient and reliable recruitment in clinical trials across various clinical faculties and health systems.

A formal standard is not available for defining and formally representing phenotyping algorithms in a standardized way. Hence the automatic or computerized translation of phenotyping algorithms to computational implementation code is not possible. In this paper, we have tried to build a formal representation of such phenotyping algorithm using EN 13606 EHR standard. Similar work has been done to evaluate openEHR standard for building computable phenotyping algorithms [1]. This attempt shall add to the learning process.

1.1 CEN/ISO EN13606 and Clinical archetypes:

The CEN/ISO EN13606 is a European norm from the European Committee for Standardization also approved as an international ISO standard [2] intended to support the interoperability of systems and components that need to communicate EHR data: EN13606 follows an innovative Dual Model architecture. The former is structured through a reference model (RM) [3] that is an object-oriented model used to represent the generic and stable properties of health record information and the later is based on clinical archetypes [4,5]. Figure 1 shows the building blocks or classes of EN13606 RM, such as Folder, Composition, Section, Entry, Cluster and Element.

An archetype is a formal and standard way of representing the clinical data structures and their inter-relationships for a given clinical domain. They are content specifications expressed in terms of constraints on a specific reference model [6]. Archetypes specify EHR clinical data hierarchies and the kinds of data values used within each entry [7].

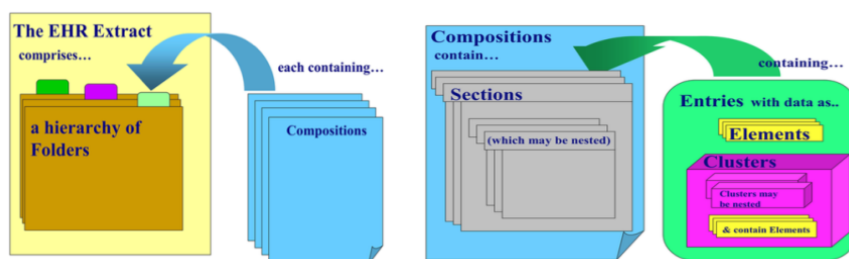

Figure 1: Structure of the reference model of EN13606 and EHR extract hierarchy [8]

2. Methods

2.1. Clinical condition/characteristic and its algorithm chosen for phenotyping:

We chose ‘cardiac failure’ as the clinical condition, diagnosis of which would need a computable phenotyping algorithm. We used a previously validated EHR phenotyping algorithm for identifying and diagnosing patients with cardiac failure. (<https://www.mdcalc.com/framingham-heart-failure-diagnostic-criteria>) The algorithm as shown in Fig. 2, represents clinical information that contributes towards the diagnosis

of cardiac failure. The algorithm was designed to identify patients with cardiac failure. Identification of various types of cardiac failure is not taken into consideration here.

2.2. Building Clinical Archetypes:

Archetypes relevant to ‘cardiac failure diagnosis’ were not found in the publicly available archetype repositories or libraries like the ‘Clinical Knowledge Manager’ by the openEHR foundation (<https://www.openehr.org/ckm/>) or ‘Ocean Informatics’ (https://www.openehr.org/industry_partners/ocean_informatics). As part of this work, we created a set of new archetypes for defining ‘cardiac failure diagnosis’ underpinned by the EHR standard EN 13606. The EN13606 editor called Object Dictionary Client (ODC) was used which was in-house developed by University College London, which is recently published, and the information models built with it are open source for use [9].

The EN 13606 Archetype describes the definitive semantic model of archetypes. It defines data types, constraints, and a reference mechanism allowing one archetype to reference another (slot). Archetypes are usually built and implemented with the help of templates, that help to combine the various archetypes together in a logical manner. EN 13606 uses the Archetype Definition Language (ADL) for building the archetypes and Archetype Query Language (AQL) for querying the data.

2.3. Desiderata for assessing clinical archetypes:

We used the desiderata published by Mo et al [10] to evaluate the ability of EN 13606 to build clinical archetypes to define EHR phenotyping algorithms. Mo et al. reviewed common features for multisite phenotype algorithms and proposed 10 desired characteristics for a flexible, computable Phenotype Record Model.

3. RESULTS

a) Archetypes created for computable phenotyping algorithm: Archetypes created were organized into a single composition with subgroups composed of number of elements (Fig. 3). Each node represents a data element, which is bound to external clinical terminologies (Read Codes, ICD-10 and SNOMED CT). Additional constraints are added to each data element including, the cardinality, optionality, datatype, value range and units for a physiological quantity, internal

Figure 2. Cardiac failure EHR phenotyping algorithm for the diagnosis of Heart failure

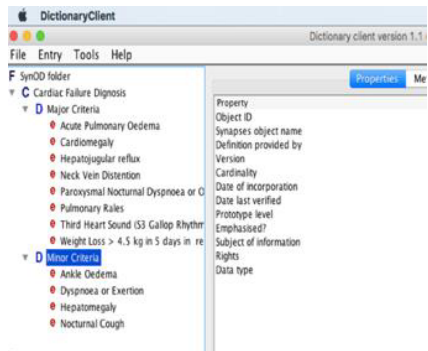

Figure 3 Clinical archetype built in ODC, an EN 13606 archetype editor

codes, etc. With EN 13606 archetypes, the components of a phenotype algorithm could be grouped or nested based on their clinical semantics into Symptoms, Signs, Investigation Results, Diagnoses, Treatment or Procedures. It can very well define the hierarchy of the data elements and the interrelationships between the data elements with the help of its Record Model (RM) properties along with the archetype slot mechanism. Still, it provides a very limited way to express the actual logic of the phenotype algorithm (especially the relational algebraic operation).

- b) Desiderata for assessing clinical archetypes: (here we have partly followed the pattern used by Papez et. Al, to represent the desiderata for assessing clinical archetypes for phenotyping algorithms) [1] Here we represent the desired desiderata [8] and where EN 13606 standard stands to satisfy it, to define phenotyping algorithms.

Table1: Summary of the feasibility of EN13606 archetypes in in defining EHR phenotyping

Desiderata by Mo. et al	Evaluation of EN 13606 EHR standard in defining computable phenotype algorithms
1. Human-readable and computable representation	Fully supported: Clinical Archetypes are defined in ADL and templates are stored as XML. EN 13606 editors can transform the archetypes (in ADL) into human-readable format such as Hypertext Markup Language (HTML) and vice versa.
2. Set operations and relational algebra	Not supported: Need to be coded and integrated with the EN 13606 clinical information model/system
3. Structured rules	Not supported: These need to be coded and integrated into the clinical information system
4. Temporal phenotype criteria	Partially supported: Archetypes support temporal criteria using points in time or time intervals. Temporal relations need to be coded within the clinical information system
5. Standardized nomenclature	Fully supported: Supports binding of the names/values of the data elements with external standardized controlled clinical terminology or classification systems (e.g. ICD-9, ICD-10, Read Codes v2/v3, SNOMED CT)
6. External interfacing	Partially supported: The entire EN13606 model can be viewed in the AWB RM schema and Class tools, and comparisons can be made with classes in the openEHR reference model.
7. Backward compatibility	Fully supported: The tracking of changes during their development and evaluation is feasible and older versions can be referred to.

4. Discussion

Since EN 13606 archetypes define the characteristics/attributes of a set of data elements and phenotyping algorithms are primarily based on identifying patients satisfying a list of criteria (e.g. signs, symptoms, investigation results, diagnosis, etc.), archetypes could be used for defining the computable phenotyping algorithms especially for their content, hierarchical structure, interrelationships of data, and temporal criteria. EN 13606 however does not satisfy all the desiderata defined by Mo et al in defining the EHR phenotyping algorithms, especially the algebraic operations and temporal relations. Natural language processing is not provided by EN 13606 and external interfacing is limited. The example of ‘cardiac failure diagnosis’ is fairly simple but more complex diagnostic criteria for various diseases would require algebraic and temporal relations to be operated and some would demand external interfacing as well.

A possible way could be an approach using phenotype ontologies and its architectural representation. The most recent published version of ISO 13606 (late 2019) refers to this approach by integrating the ISO Interoperability and Integration Reference Architecture [2] that formalizes the relationship between clinical domains and their information representation. Without that formalization, there is a risk that archetypes will proliferate to formalize pieces of a domain in disconnected and *ad hoc* ways. Ontologies can successfully formalize the representation of a domain, and therefore be an appropriate semantic anchor for the development of archetypes. With that starting point, an implementation of computable and easily searchable phenotype definitions implemented as FHIR resources is a feasible way. Furthermore, a phenotype ontology also offers rich logical relationships including the consideration of relevant context., and the desiderata defined by Mo et al. such as the delivery of structured rules, temporal criteria, etc. could be better met by the described alternative approach. By deploying the Interoperability Reference Architecture part of ISO/EN 13606, transformation between the different representation styles including archetypes can be easily performed.

5. Conclusions

EN 13606 archetypes could be used for defining the computable phenotyping algorithms especially for their contents, hierarchical structure, interrelationships of data, and temporal criteria to identify patients with a set of clinical criteria. However, it does not satisfy all the desiderata defined by Mo et al. and hence further attempts are required to achieve the objective, especially for more complex phenotyping algorithms. Clinical archetype editors underpinned by EN13606 EHR standard might need to be used along with some other programmes to make it completely feasible to represent the phenotyping algorithms. Thus, EN 13606 currently has an ability to define the computable phenotyping algorithms but has its limitations.

Generation of Fine Grained Demographic Information for Epidemiological Analysis

Timo WOLTERS ^{a,1}, Oke WÜBBENHORST ^a, Christian LÜPKES ^a and
Andreas HEIN ^b

^a *Division Health, OFFIS - Institute for Information Technology, Escherweg 2,

^b *Department of Health Services Research, Carl von Ossietzky University Oldenburg,
Oldenburg, Germany*

Abstract. Cancer risks may be influenced by local exposures such as working conditions or nuclear waste repositories. To find influences, local accumulations of cancer rates are used, for which finely granulated data should be utilized. In particular, high-resolution demographic data for a reference population are important, but often not available for data protection reasons. Therefore, estimation methods are necessary to approximate small-scale demographic data as accurately as possible. This paper presents an approach to project existing epidemiological and public data to a common granularity with respect to attribute characteristics such as place of residence, age or smoking status to allow for analyses such as local accumulations and consistently falls below an average relative error of 5%.

Keywords. Health Data Science, Data Analysis, Population Synthesis, Microsimulation

1. Introduction

The risk of cancer can be increased by the degradation of nuclear waste repositories and the associated radiation exposure of the immediate environment. Local accumulations are a type of analysis in cancer epidemiology to correlate geospatial impact with cancer risk and requires finely granular data from cancer incidences and a reference population. In epidemiological cancer registries, the reference population is often more coarsely granular than the incidences due to data protection, making an approximation of the population at the incidence level desirable. This paper presents an approach for the generation of fine-grained data using iterative proportional fitting (IPF) combined with cellular automata (CA) for exemplary application in analyses of epidemiological cancer registration (ECR) in Lower Saxony and evaluates the accuracy and reliability of the generation.

In the ECR, data is evaluated pseudonymised by the registry unit, which as a result of the analysis for the verification of a suspicion can request the underlying not pseudonymised data from the confidentiality unit [1]. In order to form a suspicion, exact results are therefore not necessary at first, since the analysis is finally carried out on the

¹Corresponding Author: Timo Wolters, OFFIS - Institute for Information Technology, Escherweg 2, Oldenburg, Germany; E-mail: timo.wolters@offis.de.

data of the confidentiality unit. However, too large an approximation error leads to false suspicions and should therefore be minimized.

Incidences are present in the ECR for Lower Saxony in a geometric grid with an edge length of 1km (1km grid) while the reference population is present at municipality level. Figure 1 shows the difference between the municipality level and a 1km grid, while the actual distribution of the population is shown in a 100m grid using the municipality of Oldenburg. The 1km grid has a much finer resolution than the municipality and better reflects the spatial distribution of the population, especially with respect to the temporal stability of a grid in contrast to frequently changing administrative boundaries of municipalities [1].

Figure 1. Granularity comparisons between a municipality, an 1km grid and an 100m grid for Oldenburg in Lower Saxony.

After Section 2 has outlined related work on population synthesis and microsimulations, Section 3 describes our approach to generate fine-granular data. Section 4 explains the implementation details and Section 5 evaluates the generation of the population, while Section 6 describes future work and summarises this contribution.

2. Related Work

Ballas et.al. investigate in [2] location-based microsimulation systems for population synthesis. Population synthesis usually combines fine granular census data with coarse granular data to approximate a synthetic population between two censuses or to add missing attributes. Population synthesis can be divided into population reconstruction, probabilistic reweighting and deterministic reweighting.

Iterative Proportional Fitting (IPF) is according to Moretti et.al. [3] a method for deterministic reweighting to map the distribution of coarse granular data (deaggregated data) to fine granular data (aggregated data). For this an unambiguous mapping between deaggregated and aggregated data is necessary. This mapping does not exist between a 1km grid and administrative boundaries of municipalities, so that IPF alone would not be sufficient to synthesize a reference population.

Basse et.al. [4] deal with exactly this problem using cellular automata (CAs) and neural networks. Cellular automata are used to simulate land use for grid cells in border regions, while neural networks are used as a probabilistic model. However, the application of neural networks requires a large demographic database, which is not available in ECR. Therefore, the combination of IPF and CA in this paper is necessary for population synthesis in order to counteract problems in border regions and insufficient data volumes.

3. Concept

For the concept, the data basis should first be considered. The aggregated data for IPF contain the demographic information with 10-year age classes and without reference to the two gender classes in a 100m grid of the 2011 census. The deaggregated data contain demographic data at municipality level with 1-year age classes with reference to the gender classes and sparsely smoker status or occupation as cancer specific attributes. Additional data are information from the census on households and families and are used in the integration of CA with IPF. From the deaggregated data, statistical ratios such as the proportion of a 1-year class in a 10-year class are extracted as additional information.

This results in a vector $U = \{U_1, U_2, \dots\}$ of attributes that are to be generated with a function $P_{U,C}$ by assigning a probability $p_{i,j}$ to each attribute characteristic $u_{i,j} \in U_i$, taking into account the deaggregated data as context C . $P_{U,C}$ gets as argument a vector $A = \{a_1, a_2, \dots\}$ of the aggregated data so that a random number $\pi \in [0; 1]$ together with A calculates a vector $u = \{u_1, u_2, \dots | u_i \in U_i\}$ representing a single person with all required attributes. A CA then checks the conformity of the generated data with the family, household and demographic data and gradually adapts the demography so that the information on families and households is reflected in the demographic data, but meets the constraints of the municipality demography.

In the application, $U = \{age, gender, residence\}$ is used with 1-year age groups up to 80 and the 100m grid of the census as a place of residence. The vector $A = \{age_{10}, residence, gender_n, households, families\}$ contains the 10-year age groups up to 80 of the census, the same place of residence and the number of men and women living in the grid cell together with the information on families and households for the CA. Other attributes such as smoker status or hormone receptor information for lung cancer or breast cancer, for example, are also possible for U and A if the necessary data are available. Based on epidemiological cancer registration, smoking status information is rare and hormone receptor information is not available, but hormone receptor information should be reported in the clinical cancer registration for estrogen in breast cancer.

After generation, an additional function \bar{p} is applied, which can serve as a bias. \bar{p} is particularly useful if generation is to be carried out for years other than the census year, since population changes and changes in administrative boundaries can be modelled here. On the other hand, this function can be used to correct inconsistencies between different data sources.

4. Implementation

The data of the census are available in tables with about 6 columns, but 61 million entries. Partitioning based on characteristics (age, gender) is essential to shorten access times

to the data. The geo references of the census are used to link the sub-data sets of the aggregated data and a mapping to municipalities is used to link the deaggregated data.

Population synthesis uses IPF for an initial statistical distribution of personal characteristics in the grid cells of the municipality. On the basis of this distribution, CA is used to generate people probabilistically until the statistical distribution is approximated, taking into account household and family data, or a certain number of iterations has been reached. However, the average number of persons per grid cell is 6, so that the empirical law of large numbers cannot be applied to the probabilistic method to approximate the statistical distribution. An adaptation of probability from [5] helps to achieve faster convergence despite small numbers of people. For this purpose, logistic growth is used as an adaptation function with the turning point $(1, p_i)$ for the basic probability of a feature, and the limits are defined by $p_u = 1.5 \cdot p_i$ and $p_l = 0.5 \cdot p_i$. The abscissa x counts the occurrence of an event and the higher x is, the greater the probability of the counter-event, whereby the occurrence of the counter-event x can either be set to 1 (hard reset) or reduced by 1 (soft reset). \bar{p} is trained with municipality data from the census year 2011 and a target year, e.g. 2017, so that the generation can also be used for other years.

5. Evaluation

The evaluation of the data quality on the 1km grid is not possible, because data with comparable accuracy are missing. Instead, the generated 100m grid cells of the map step are aggregated at the municipality level and compared with the previous municipality data for the year 2011. \bar{p} thus has no influence on the data quality, since the identity function is used for 2011. Since the procedure is probabilistic, several iterations should be considered for evaluation. The influence of probability adaptation (PA) should also be measured to determine the necessity and contribution to stability of the adaptation. A total of 12 iterations with and without probability adaptation were performed, with Figure 2 showing the best results of the iterations based on the relative error for the generated gender distribution in the municipality average.

Figure 2. Relative error in Lower Saxony in 2011 with and without probability adaptation.

The total plots in Figures 2a and 2b are identical and reflect the relative error of the number of persons generated between the 100m grid and the municipality level. The aim of the procedure should be to distribute the error as evenly as possible over the individ-

ual characteristics in order to achieve stable convergence. The generation without PA in Figure 2a shows a clearly higher variance, in particular the even distribution of the error on the characteristics does not take place, because a low error for one gender results in a high error for the other gender. Without PA, for example, the maximum error can vary between 4% and 12%, while with PA it can vary between 7% and 8% as Figure 2b indicates. Overall, PA is necessary as a factor for the stabilization and reliability of the procedure, whereas the synthesized population for Lower Saxony deviates from the actual population by an average of 2.7% and can therefore be used for the analysis of local accumulations.

6. Conclusion

Currently, \bar{p} is used for 2011 as an identity function or to represent the population for other years. It is conceivable that this function can also be trained to minimize errors, so that overall errors and thus also the generation error of the characteristics decrease and can lie within the 99% confidence interval. In addition, the procedure can also be used for regions other than Lower Saxony or for data with other granularities. Furthermore, the method can also be applied for the approximation of health information described in [6], e.g. supply chain company networks on different levels (personnel, specialist groups, company groups) for drug research or for clinical studies, in order to dissolve clusters if necessary and to reduce study costs by data approximation in preliminary studies.

This paper has given an overview of various granularities of demographic data in epidemiological cancer registration and a probabilistic procedure for approximating actual demographics for a 1km grid using a combination of Iterative Proportional Fitting (IPF) and cellular automata (CA). For this purpose, municipality-level data were combined with data from the 2011 census for Lower Saxony, so that a statistical distribution was created by IPF as a framework for the actual generation of the population by CA in a 100m grid. The generation error in relation to known data is on average 3%, but a detailed evaluation on 100m or 1km grids was not possible because no reference data were available.

Abstract. One major obstacle to developing precision medicine to its full potential is the privacy concerns related to genomic-data sharing. Even though the academic community has proposed many solutions to protect genomic privacy, these so far have not been adopted in practice, mainly due to their impact on the data utility. We introduce GenoShare, a framework that enables individual citizens to understand and quantify the risks of revealing genome-related privacy-sensitive attributes (e.g., health status, kinship, physical traits) from sharing their genomic data with (potentially untrusted) third parties. GenoShare enables informed decision-making about sharing exact genomic data, by jointly simulating genome-based inference attacks and quantifying the risk stemming from a potential data disclosure.

Keywords. genomic privacy, privacy-conscious tools, risk quantification, inference

1. Introduction

The growing number of health data breaches [1] and the recent revelations about the use of free genealogical databases for law enforcement purposes [2] are increasingly eroding public trust in social media, genealogy websites (e.g., 23andMe and Ancestry.com) and personalized medicine initiatives (e.g., the U.S. All of Us Research Program and the U.K. 100,000 Genomes Project), worldwide. Guaranteeing individuals' genetic privacy is becoming a major challenge for those who want to encourage sharing of medical data for research purposes and better personalized medicine. In response to this demand, the computer security community has made a remarkable effort in providing solutions to secure the storage [3], and the processing of genetic data [4,5,6,7,8]. Yet, the issue of trust goes beyond the provision of secure storage and processing. It is also intimately related to the question of *control* over what data is shared and what information it conveys. In

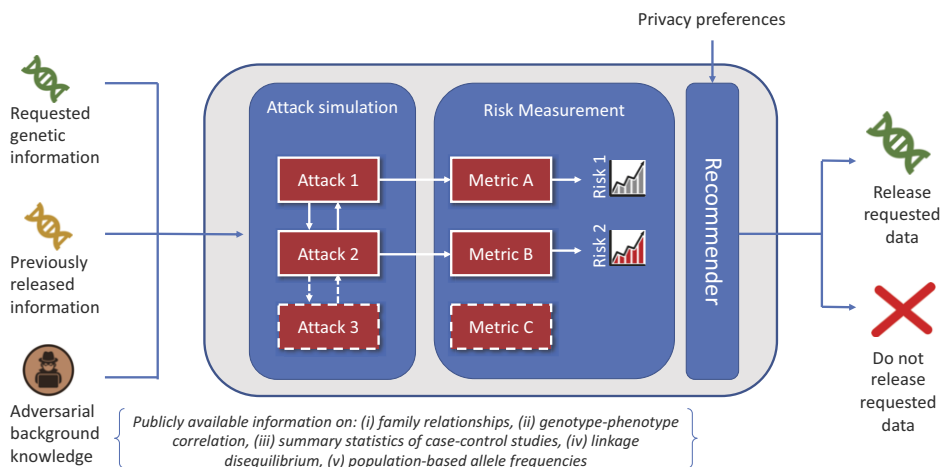

Figure 1. High-level representation of the GenoShare framework.

this paper, we introduce *GenoShare*, the first decision-support framework that provides individuals with guidance at the time of deciding what data can be shared without risking the undesired disclosure of sensitive information.

2. Methods

Let's assume an individual wishes to share part of her genetic profile with a public or private third party in order to join a personalized medicine study or obtain some genetic-related services, but she is concerned about her genetic privacy. Upon reception of a request for genetic data sharing, such an individual can use *GenoShare* to quantify the risk of sensitive attribute disclosure associated to revealing those data. To this end, *GenoShare* simulates the combination of inference attacks relevant to the privacy concerns of the individual (e.g., revealing the participation in a sensitive study, revealing undisclosed kinship, revealing predisposition to certain health conditions) and, based on the information available to the adversary, measures the risk of a potential privacy breach. We consider that a realistic adversary could have access to: (i) part of the individual's genetic profile obtained in the past, (ii) the statistical regularities within the genetic population to which the individual belongs (e.g., linkage disequilibrium, allele frequencies), (iii) the effect-size statistics of the genotype-phenotype association, (iv) the genetic profiles of the individual's relatives who might have already joined the study, and the (v) aggregate statistics from other studies in which the individual might have participated. *GenoShare* is a modular framework and enables different parameterizations (i.e., different levels of adversarial prior knowledge) and the instantiations of different inference attacks, according to the data-sharing context (Fig. 1). Furthermore, *GenoShare* provides a mechanism, based on the generation of synthetic genomes called *avatars*, to protect individuals' genetic privacy from inferences stemming from decision to not release the requested data. Details about the algorithms underpinning *GenoShare* are described in the extended version of this paper [9].

3. Results

To show how GenoShare can, in practice, support privacy-conscious decisions when sharing genetic data, we implement an operational prototype in Python with a Web user interface. We instantiate it with three of the most important genomics-oriented inference attacks that we re-adapted to work on a joint manner and on adversarial partial knowledge: the phenotype inference attack, the membership inference attack and the kinship inference attack. For our experiments, we used individual genetic profiles from the 1,000 Genomes Project [10] and considered different data-sharing use cases where the adversary has access to an increasing amount of information about the targeted individual. For example, for a given individual, GenoShare shows that revealing her genetic variants related to schizophrenia (400 variants) introduces a risk of almost 100% of leaking the value of her predisposition to bipolar disorder and her participation in a study with less than 50 people, and a risk of 60% of leaking her kinship with a first-degree relative who might be known by the adversary. Details and figures about the experiments run to validate GenoShare are described in the extended version of this paper [9].

4. Discussion

Academic solutions for privacy-preserving sharing of genetic data that provide formal guarantees of privacy, such as differential privacy, have mostly focused on data perturbation (e.g., differential privacy). Such solutions, however, have not been adopted by the medical sector as (i) they are only suitable for protecting genetic privacy when aggregate information is shared and (ii) they damage the utility of the data such that is then unusable by practitioners. As opposed to these solutions, GenoShare quantifies the risk of sensitive attribute disclosure when *individual and exact* genetic data is released by using novel meaningful sensitive attribute-oriented metrics and by considering realistic adversaries with limited and parametrizable background knowledge. Finally, to the best of our knowledge, GenoShare is also the first framework to jointly consider relevant attacks in genomic privacy in presence of incomplete information. Therefore, it provides a principled answer to the privacy concerns that affecting the genomic community, and thus it is a firm step forward to enable the responsible and privacy-respecting use of genomic data in research and medical environments.

H-Accuracy, an Alternative Metric to Assess Classification Models in Medicine

Andrea CAMPAGNER ^{a,b}, Luca SCONFENZA ^b and Federico CABITZA ^{b,1}

^a *IRCCS Istituto Ortopedico Galeazzi, Milano, Italy*

^b *University of Milano-Bicocca, Milano, Italy*

Abstract. As widely known, regular accuracy is a misleading and shallow indicator of the performance of a predictive model, especially in real-life domains like medicine, where decisions affect health or life. In this paper we present and discuss a new accuracy measure, the H-accuracy, as a more conservative alternative to regular accuracy, which we claim is more informative in the medical domain (and others of similar needs) for the elements it encompasses. In particular, the proposed measure takes into account important information such as the complexity of the cases and the case prevalence in the population. We also provide proof that the H-accuracy is a generalization of the balanced accuracy and illustrate the descriptive power of this score.

Keywords. Accuracy, Machine Learning, Medical Artificial Intelligence, Validation

1. Introduction

Statistical and machine learning communities have developed many metrics to assess and report the predictive performance of a model [1]: some metrics are common and easy-to-comprehend, like accuracy, recall (also known as sensitivity), specificity, the F_1 score (i.e., the harmonic mean of sensitivity and specificity), and the area under the ROC curve (AUROC); others are less common and less straightforward, like the Cohen's Kappa, the Gini coefficient, cross-entropy and Hamming loss.

However, in the non-specialist literature, like medicine, one measure of model performance is much more common than the others: *accuracy*, that is the proportion of correct predictions with respect to the total number of predictions made. Despite its apparent simplicity, accuracy scores can be misleading. For instance, it is generally well known that on imbalanced datasets high values of the accuracy of a model could mirror overfitting with respect to the majority class. In case of datasets where classes are unevenly represented, an alternative measure has been proposed instead of regular accuracy: *balanced accuracy*, that is defined as the average accuracy obtained on each class individually. It can easily be shown that increasing the difference in the prevalence of the two classes of a binary discriminative task makes regular and balanced accuracy diverge pro-

¹Corresponding Author: Federico Cabitza, federico.cabitza@unimib.it

gressively, so that the meaningfulness of the former and more common type of accuracy, which is blind to class prevalence problems, can be disputed¹ [2].

We also believe that regular accuracy is only a partial way to convey meaningful information on the usefulness and practical value of a predictive model, mainly because it overestimates the model performance and does not take into account important characteristics of the test set, like the class (im)balance, the complexity of the cases correctly identified or the importance of rightly detecting one class at the expense of the other(s), according to the users' preferences.

In this paper we present a new accuracy measure, the H-accuracy, or Ha , which we claim is more informative in the medical domain (and other domain with similar requirements) as it covers all of the aspects mentioned above.

2. Method

In the following we deal with a classification task in which the set of classes (or labels) is $C = \{l_1, \dots, l_k\}$; we have a dataset of instances $S = \{x_1, \dots, x_n\}$ sampled from the space of all possible observations X and the real class of instance x is given by a function $c : X \rightarrow C$. We consider, without loss of generality, only *scoring models*: that is, models m defined as $m : X \rightarrow [0, 1]^k$ where, given $m(x) = (l_{1m}(x), \dots, l_{km}(x))$, where $l_{im}(x)$ represents the *confidence* attached to the event $c(x) = l_i$. We also define $\mathbf{m}(x) = \text{argmax}_{l_i} l_{im}(x)$ as the prediction of m . Accuracy of a model m is defined as $a(m) = \frac{1}{|S|} \sum_{x \in S} \mathbb{1}_{\mathbf{m}(x)=c(x)}$, while *Balanced accuracy* is defined as $Ba(m) = \frac{1}{|C|} \sum_{l \in C} \frac{1}{|\{x \in S : c(x)=l\}|}$.

We then introduce the formula for the H-accuracy of a model m as:

$$Ha(m) \Big| \tau, \mathbf{p}, \mathbf{d} = \sum_{l \in C} (\mathbf{p}(l) * \sum_{x \in S : c(x)=l} \frac{\mathbf{d}(x)}{\sum_{c(x)=l} \mathbf{d}(x)} * \sigma_m(\mathbf{l}(x)|\tau)) \quad (1)$$

Where:

1. $\mathbf{p}(l)$ is the *priority* associated to class $l \in C$ (with $\sum_{l \in C} \mathbf{p}(l) = 1$, that is a representation of the relative importance attached to the fact that the model correctly predicts that label;
2. $\mathbf{d}(x) \in [0,1]$ is the complexity of instance x , that is the intrinsic difficulty of making the correct prediction about the case x ;
3. $\mathbf{l}(x)$ is the prediction score for class l on instance x ;
4. $\sigma(\mathbf{l}(x)|\tau)$ is defined as ²

$$\sigma(\mathbf{l}(x)|\tau) = \begin{cases} 0 & \mathbf{l}(x) < \max_{c \in C} \mathbf{c}(x) \\ \frac{\mathbf{l}(x) - \frac{1}{|C|}}{\tau - \frac{1}{|C|}} & \max_{c \in C} \mathbf{c}(x) \leq \mathbf{l}(x) \leq \tau \\ 1 & \mathbf{l}(x) < \tau \end{cases}$$

¹ The same problem affects the area under the ROC curve, another very common performance metrics in medical AI.

² Notice that when $\tau = \frac{1}{|C|}$ the function is defined as $\sigma(\mathbf{l}(x)|\tau) = \begin{cases} 0 & \mathbf{l}(x) < \max_{c \in C} \mathbf{c}(x) \\ 1 & \mathbf{l}(x) \geq \max_{c \in C} \mathbf{c}(x) \end{cases}$

It is easy to prove that Ha is a proper generalization of the balanced accuracy (Ba) and, thus, a proper accuracy measure:

Proposition 1. Let $C = \{l_1, \dots, l_k\}$ $\tau - \frac{1}{|C|}, \forall i. p(l_i) = \frac{1}{|C|}$ and $\forall x \in X. d(x) = k \in [0, 1]$. Then $\forall h. Ba(m) = Ha(m|\tau, p, d)$.

3. Discussion

In this section, we will share some reflections on the different kinds of accuracy scores that Formula 1 allows to produce, and on the methods that can be applied to set the τ , p and $d(x)$ parameters.

3.1. Confidence, for reliability

First, let us consider *confident accuracy* (i.e. $Ha(\tau) = Ha(m|\tau, \frac{1}{|C|}, k)$), according to values of τ , that is the accuracy of a system that is at least τ , *confident* of its output, such that we can claim that “it does not take guesses”.

This measure finds motivation in how human experts behave: in situations of uncertainty they “don’t usually toss a coin” ($\tau = 50\%$) but rather abstain, at least temporarily, and either look for stronger clues or evidence [3], or refer to the second opinion of a more expert colleague [4]. When multiple options are available (i.e., in multi-class tasks), experts can choose the option (e.g., the diagnosis) that is more likely or plausible among the ones available, but they would still act as the option were true only when the plausibility is high enough (otherwise, at least in medicine, a “wait and see” attitude is generally recommended [5]).

Although there are some machine learning applications that apply abstention in conditions of uncertainty [6], this approach is not commonly adopted, and hence it is common that decision support systems have users considering recommendations that are associated with low prediction scores and have a higher chance to be wrong, often without their knowledge, and hence mislead them. Setting a τ , and reporting a corresponding confident accuracy ($Ha(m|\tau)$), can help users evaluate this risk.

Setting a high τ and relying on Ha instead of regular accuracy raises the bar for the performance of machine learning in real-world settings and reflects the requirement to have really accurate models that minimize “guessing” behaviors in a sensitive context.

3.2. Priority, for tailorability

Prioritized accuracy (i.e., $Ha(p) = Ha(m|\frac{1}{|C|}, p, k)$) is defined according to p values. These can be set naively: if $Ha(m|p)$ must express a clear preference for specificity, p could be associated with 0.75 (and 0.25 with respect to sensitivity); and vice versa in case of a preference for sensitivity. Otherwise, if no preference is expressed, a balanced weighting $p = .5$ can be adopted.

On the other hand, priority p can be set empirically in two ways: either explicitly or implicitly. The explicit way entails to collect the preferences of a panel of experts for the classification task at hand by means of a psychometric questionnaire. The implicit case occurs when experts are involved as dataset labelers, and p is set according to their performance.

3.3 Complexity, for usefulness

With the term *complexity*, as hinted above, we refer to decision effort and difficulty to classify an instance for the test set.

But how should $d(x)$ be determined, and hence the *practical accuracy* (i.e. $Ha(d) = Ha(m|\frac{1}{|C|}, \frac{1}{|C|}, d)$) score? Here, we recall that $d(x)$ is a function returning a complexity score for each case x , that is how hard it is to correctly classify the case. This function can be determined in different ways, among which we can distinguish between direct and indirect methods. In regard to the former approach: we can ask the doctors involved to express whether they found a case x difficult or not (0 or 1), as if we asked them if that case deserves to be shared with a class of residents or trainees, or even with the specialist community, as a case report [7]. Similarly, we could ask them to rate how difficult they perceived the case x on an ordinal scale.

Alternatively, once a gold standard is available or has been established, also indirect methods are possible; for instance $d(x)$ can be set on the basis of the error rate of the raters involved for that specific case x : the higher, the more difficult the case is; or on the basis of the confidence the raters express in assessing the case, irrespective of whether their answer was correct or not.

Why assessing complexity is important, and therefore *practical accuracy* is? Think of a very accurate decision support for trivial or easy cases: the medical experts would not consult it, or if they do, would neglect and override it with no regret or doubt in case they disagreed with it³. Conversely, complex cases are those for which even experts would like to receive confirmation or, if lost about them, a proper aid. In these cases, right advice can have a strong impact on the final decision, and wrong advice can mislead the decision makers, a situation that could be worsened by automation bias (i.e., over-reliance on the support, which could be induced by a higher, almost oracular, accuracy exhibited by the system on the easy cases).

For these reasons, we deem the *practical accuracy* an important measure to compute and report, to understand the real utility of a decision support in naturalistic (i.e., real-world) decision making by expert practitioners.

4. Conclusions

In this paper we aimed to raise awareness that the medical community (like many others that increasingly rely on predictive models and decision support systems) must have single, summative but yet comprehensive and informative ways to report and communicate model performance and skills. Other contributions have discussed the limits of common performance measures (e.g., the AUC [8] and accuracy itself [9]) and proposed how to minimize the odds of misinformation about model performance. In addition to this body of literature, we make the claim that the current use of the accuracy indicator for understanding and reporting how well a model works (even assuming a proper testing process producing such an indicator) falls short of communicating the most important feature of a decision support, that is being useful in daily practice.

³Let us just hint at the impact of these "easy misses" on doctors' trust and on the perceived reliability of the support.

Different research groups and companies across the world in the domain of machine-learning based decision support struggle to surpass competitors even by a few percentage points in accuracy (or related measures), with a common “psychological” threshold to interest the medical stakeholders set to 80% at least [10]: besides these figures, in this paper we make the point that is more important to inform stakeholders and practitioners by also showing them alternative and more conservative accuracy measures, with a *clear clinical and practical meaning*.

For this reason, in this paper we proposed a general formula that takes into account the reliability and relevance of the advice given; we also pointed out meaningful areas of the resulting function to focus on specific aspects of the model performance, like reliability (cf. *r*), practicality (cf. *d*) and priority (cf. *p*), and some empirical values to report a set of accuracy measures that could inform the users adopting a model exhibiting such skills, namely *confident*, *prioritized*, and *practical accuracy*.

These measures regard a *static* assessment of the accuracy of a prediction model, evaluated *holistically* on a whole test dataset, as an indicator of the usefulness of the model. Our future work will explore a more dynamic and case-dependent assessment, yielding indicators of the reliability of the model’s predictions: this is the case of a sort of *local accuracy* metrics, that is related to the single new case to classify, evaluated on the basis of the performance of the model on the *n* (e.g., 10) most similar cases in the test set, as a function of their similarity to the new case at hand.

Once more comprehensive static metrics and convenient dynamic metrics have been made available to the users, further research should be aimed at evaluating as the user experience could change and possibly improve when decision makers can learn these additional information about their decision support [11], to mitigate automation bias and increase meaningful use and the overall accuracy of a community of decision makers in real-world settings.

Abstract. *Introduction.* Electronic health records (EHR) comprehend structured and unstructured data, that are usually time dependent, enabling the use of timelines. However, it is often difficult to display all data without inducing information overload. In both clinical usual care and medical research, users should be able to quickly find relevant information, with minimal cognitive overhead. Our goal was to devise simple visualization techniques for handling medical data in both contexts. *Methods.* An abstraction layer for structured EHR data was devised after an informal literature review and discussions between authors. The “Heimdall” prototype was developed. Two experts evaluated the tool by answering 5 questions on 24 clinical cases. *Results.* Temporal data was abstracted in three simple types: events, states and measures, with appropriate visual representations for each type. Heimdall can load and display complex heterogeneous structured temporal data in a straightforward way. The main view can display events, states and measures along a shared timeline. Users can summarize data using temporal, hierarchical compression and filters. Default and custom views can be used to work in problem-oriented ways. The evaluation found conclusive results. *Conclusion.* The “Heimdall” prototype provides a comprehensive and efficient graphical interface for EHR data visualization. It is open source, can be used with an R package, and is available at <https://koromix.dev/files/R>.

Keywords. Electronic health records, Visualization, Timeline, Feature extraction.

1. Introduction

Electronic health records data usually contain structured data, such as administrative data, diagnoses (e.g. ICD10 codes [1]), procedures, administered drugs, medical devices, laboratory results, and non-structured data, such as free-text medical records and medical imaging. All of them are characterized by their temporal aspects (e.g. the date of a measurement, the period of a diagnosis, etc.), and relate to one patient. Structured data often take the form of multivalued qualitative variables, encoded using terminologies, and supported by a hierarchical tree of sections and codes.

Data visualization is interesting within 2 contexts. “Transactional” visualization relates to visualization of one patient’s data, in order to provide the patient with appropriate care. “Decisional” visualization relates the visualization of several patient’s data, for management or research purposes [2,3], notably in the frame of data reuse.

In both contexts, the main objective of data visualization is to provide the user with a comprehensive view, and to enhance the mental process of feature extraction [4], by making it easy to detect temporal associations. For instance, in case of INR elevation and red cells decrease, a physician infers the patient encountered a hemorrhage. However, data complexity may overload the user, leading to interpretation errors [5].

Many visual interfaces have been developed for transactional EHR data visualization [6], such as *LifeLines* [7], *MultiMedia Stream System (MMSS) TimeLine* [8], *KNAVE-II* [9], *TimeLine* [10] *HARVEST* [11], or other prototypes [12–14]. However, to our knowledge, such representation methods are rarely implemented in commercial hospital information systems. Some visual interfaces have also been developed for decisional EHR data visualization, such as *OutFlow* [15], *Care Pathway Explorer* [16], *EventFlow* [17], or other prototypes [18–25]. Many of them are dedicated to specific tasks. The objective is to propose a visualization method that could either be used for transactional or decisional visualization of EHR data, and to evaluate it.

2. Method

An abstraction layer for EHR data was first defined, based on an informal literature review, and discussions between authors, taking profit from their experience in clinical care and data reuse. The prototype was intended to be embeddable in C++ programs, R [26], and web pages.

To evaluate the tool, two medical experts (not involved in the development) were asked to retrieve medical information over 24 cases of acute kidney injury (AKI, according to the KDIGO criteria [27]). The 24 cases were represented through 3 interfaces: the classical interface (“classical”: 1 page per type of information, with tables), the manually optimized interface (“manual”: the same, but manually filtered, to present only relevant data), and the Heimdall interface (“Heimdall”: developed in this project, without any prior data filtering). Expert *A* used “classical” to evaluate records #1-8, “manual” for records #9-16, and “Heimdall” for records #17-24. Expert *B* used the same interfaces respectively for records #17-24, then #9-16, then #1-8. Both experts were asked to answer five questions for each case (“d0” relates to the date of AKI, which was intentionally not explicit): (Q1) Was a nephrotoxic treatment discontinued, at d0 or d1? (Q2) Was there a urine dosage of sodium and potassium, at d0 or d1? (Q3) Was there a search for proteinuria, at d0 or d1? (Q4) Was there a urinary tract imaging at d0, d1 or d2? (Q5) Was there an ICD10 code of AKI? Number of errors and time required to answer were compared using an analysis of variance.

3. Results

3.1. EHR data abstraction

We identified 3 types of information: (1) *events*, which occur at a single point in time, and have a label and a date (e.g. a medical procedure, a document), (2) *States*, which are

characterized by a label, a start date and a stop date (e.g. a hospital stay, a diagnosis), and (3) *Measures*, which are characterized by a date, a label and a value (with or without normality range; e.g. a laboratory result, a clinical parameter).

For each of kind of information, the label could be part of a hierarchical tree. In such case, the hierarchy folding had to result in the merging of the symbols. Moreover, additional information could be provided, e.g. the content for a document, which is a sort of *event*, or the unit for a laboratory result, which is a sort of *measure*.

3.2. Prototype development

Heimdall is a read-only visualization tool, developed in C++, using OpenGL, and Dear ImGui. It is available for MS Windows and GNU/Linux. It can be used through its R package, which enables data loading and terminology handling, and can also be integrated inside web pages (through WASM and WebGL).

Pieces of data relating to the same data type are grouped into a component (e.g. 3 values of blood potassium → a unique curve of kalemia). Each component follows a time axis from the left to the right. Components are designed to be stacked vertically.

Figure 1 shows the representation of components according to their type, and their behavior in case of combination (e.g. in case of terminology folding or temporal compression). *Events* are represented as triangles, *states* as transparent rectangles, and *measures* as curves. When folded, measures are transformed into red events in case of abnormal values (outside normality range), or blue events otherwise. The interpolation method can be set as Last Observation Carrier Forward, linear, or cubic spline.

Figure 1. Unfolded and folded representation of 3 types of components

Figure 2. Example of a medical record (partially unfolded view)

Figure 2 illustrates a medical record. The main window principally looks like a stack of components, with a unique time axis. The components are organized according to their hierarchy: (1) patient, then (2) data type (e.g. diagnoses, laboratory results, etc.), then (3) the hierarchical tree of the relevant terminology, if so (e.g. ICD10). This organization is

compatible with both transactional (one patient) and decisional (several patients) usage. In case of multi-patient view, the time axis can be aligned with real dates, or with a chosen event (e.g. birthdate, first inpatient stay, or specific surgical procedure). The representation of big amount of data is made easier by 3 mechanisms: (1) the time axis can be rescaled using control key plus mouse wheel, (2) the top-bottom axis can be compressed, resulting in components folding, and (3) a dropdown menu enables for quick use of problem-oriented filtered views. For instance, the “renal” view only shows diagnoses, procedures, laboratory results and drugs in relation with the kidneys or the renal function. The user can create custom views.

3.3. Prototype evaluation

Loading data from 3,500 patients, including 360,000 values, in Heimdall from R took a couple seconds on a workstation equipped with an old Intel® Core 2 Duo CPU (2009), and required about 50 MB of memory (40% for non-character data, 30% for character data, and 30% for terminologies/graphic interface/polices).

The results of the evaluation are presented in Table 1. For both users, the manually optimized interface and the Heimdall interface were faster to use than the classical interface. The number of errors did not significantly differ.

Table 1. Results of the evaluation (2 experts * 24 clinical cases * 5 questions)

Expert	Measure	“Classical”	“Manual”	“Heimdall”	<i>p val.</i>
#1	Time required (sec, mean & SD)	54.25 (5.42)	35.00 (2.62)	40.88 (5.22)	< 0.001
	Errors (n & %)	0.38 (0.74)	0.12 (0.35)	0.25 (0.46)	0.662
#2	Time required (sec, mean & SD)	57.75 (6.82)	42.25 (5.23)	45.38 (4.47)	< 0.001
	Errors (n & %)	0.38 (0.74)	0.12 (0.35)	0.12 (0.35)	0.546

4. Discussion and conclusion

In this work, we designed a data visualization prototype called “Heimdall”, and evaluated it. The Heimdall interface takes profit from combining foldable hierarchical view with a timeline. Alignment, filtering and custom views enhance data exploration. Heimdall is very fast and easy to use. However, this tool is still not able to display non-temporal data (e.g. birthdate), or data with imprecise timing (e.g. ancient medical history). Non-structured data can be displayed as document icons. Unlike EventFlow [17], Heimdall only provides rudimentary tools for querying and filtering data. The problem-oriented filtering seems to be the most powerful part. Heimdall provides a comprehensive and efficient graphical interface for EHR data visualization. It is open source, and the current R package (alpha version) can be downloaded at <https://koromix.dev/files/R>.

How Have Experimental Cancer Interventions Evolved over Time?

Ziran LI^a, Huanyao CHEN^a, Chi YUAN^a, Chunhua WENG^a

^aDepartment of Biomedical Informatics, Columbia University, New York, NY, USA

Abstract. We performed a trends analysis of experimental cancer interventions. The complete records of 32,623 interventional neoplasm clinical trials involving 454 types of neoplasms from 2000 to 2017 were downloaded from the AACT database. The conditions and drug concepts were normalized using MetaMap. The normalized frequencies (NF) for each type of intervention were calculated and compared. Among 95,440 interventions, 77.4% were drugs, 5.3% were radiation, 6.6% were surgery and 10.6% were other therapies. Among 47,754 arms, 82.8% were mono-type interventions and 17.2% were multi-type interventions. Among 73,889 drug interventions, immunologic factor drugs increased rapidly over the last five years. Both breast cancer and pancreatic cancer have been testing new drugs in clinical trials; however, more drugs have been tested in phase 3 or 4 trials and employed in comparator arms for breast cancer compared to pancreatic cancer. Breast cancer trials showed a more even drug NF distribution than pancreatic cancer trials. The JS Distance among three periods (2000-05 vs. 2006-11 vs. 2012-17) showed unidirectional research progress trend for breast cancer, but reverse trend for pancreatic cancer. This study contributes a large-scale landscape overview of the trends in cancer experimental interventions and a methodology for using public clinical trial summaries for understanding the evolving cancer research.

Keywords. Clinical Trials, Trend Analysis, Data Science

1. Introduction

The World Health Organization predicted that worldwide cancer cases are projected to increase by 50% by 2030, from 14 million to 21 million. Well-identified progress in cancer research is pivotal for our understanding of the cancer research direction. Many systematic reviews have uncovered the unbalanced medical advances across different cancers. While prior studies reviewed the evolution of cancer treatment and highlighted the advances in specific cancer types, they are unable to spark more far-reaching insight due to several potential study limitations. *Firstly*, these studies have largely focused on one cancer at a time. *Secondly*, only a qualitative description of the milestones in the cancer treatment history is given based on the reports of domain experts. A longitudinal quantitative analysis is needed to investigate multiple cancer types together to help us better understand the progress in a big picture, compare advances in cancer treatment across different interventions, and guide the future development of cancer therapies. The ClinicalTrials.gov houses all trials including eligibilities, conditions, study design, interventions, result and outcome information. In this study, we propose quantitative methods to answer two questions: (1) What types of interventions have consistent patterns across cancers? (2) What are the trends of intervention research across cancers?

2. Methods

2.1. Dataset

As of July 2018, the record of 271,514 distinct clinical trials were all downloaded from the database of Aggregate Analysis of ClinicalTrials.gov (AACT) [1]. First, interventional studies with primary purpose of treatment conducted within 2000 to 2017 were extracted. Then, an oncology interventional clinical trial dataset was created by selecting clinical trials whose condition MeSH term has the semantic type of “neoplastic process”. The information of treatment arms and interventions were extracted. Each intervention in the clinical trial was recognized as an instance that we focused on.

2.2. Data Preprocessing

Clinical trial conditions were mapped to MeSH concepts. Then all free-text drugs extracted from table of interventions with either “Drug” or “Biological” intervention type were mapped to NCIt concepts using MetaMap. All neoplastic trials were assigned to one of three time periods including 2000-2005 (1st period), 2006-2011 (2nd period), and 2012-2017 (3rd period). The phases of clinical trials were modified as “Phase 1/2” or “Phase 3/4”. Each treatment arm was modified as “experimental” or “comparator” arm type based on the value of group_type field. The interventions were classified into four intervention types, including drug (“Drug” or “Biological”), surgical procedure, radiation, and other therapies (includes “Dietary Supplement”, “Behavioral”, “Device”, “Genetic”, and “Other”). Mapped drug concepts were classified into three drug types based on the UMLS semantic type of the concept, which are immunologic factor (semantic type is “Immunologic Factor”), other bioactive substance (“Hormone”, “Enzyme”, “Vitamin”, “Receptor”, or “Biologically Active Substance”), and conventional drugs (“Pharmacologic Substance” or “Antibiotic”). All interventions in our dataset were stamped with the time period, cancer type, modified phase, modified arm type, modified intervention type, and drug type (only for drug intervention).

2.3. Trend analysis of Intervention Pattern and Drug

We defined the normalized frequency (NF) as the number of interested intervention divided by the total number of interventions for studied condition(s) during a certain time period. The NF of each type of intervention in each year were calculated and compared. We interpreted the change of NF along time as the trends of intervention types. Two types of interventional patterns were defined based on the combination of different types of intervention: mono-pattern includes one type of intervention, such as drug, surgery, radiation or other therapies, while multi-pattern includes the combination of at least two different types of intervention.

We took breast neoplasm and pancreatic neoplasm as examples to demonstrate the different drug research trends across different neoplastic diseases. Breast neoplasm was identified by collecting condition concepts with UMLS CUI including C0006142, C0242788, C0021367, C0206692, C0677776, C0278601, C4018978, C3539878, and C1458155; Pancreatic neoplasm was identified by collecting condition concepts with UMLS CUI including C0030297, C0242363, C1328479, and C0887833. For each trial, we first removed drugs in comparator arms from the drugs in experimental treatment arms to extract research drugs for each trial. The NFs of all research drugs were

calculated in each period. All NFs in each period formed a density distribution of drug tested times in clinical trials. Jensen-Shannon (JS) distance was used to quantify the change of drug distribution among three periods. The density distributions for most popular research drugs were visualized and compared. The number of tested times for most popular research drugs stratified by arm types or trial phase were also visualized and compared between two types of neoplasm.

3. Results

3.1. Clinical trial retrieval and concept recognition

A total of 32,623 neoplastic clinical trials with 47,754 treatment arms encompassing 95,440 interventions were identified, with 73,889 (77.4%) being drugs, 5,048 (5.3%) being radiation, 6,330 (6.6%) being surgery and 10,137 (10.6%) being other therapies. Among 47,754 treatment arms, 39,530 (82.8%) arms were mono-pattern, 8,224 (17.2%) were multi-pattern. The number of newly registered neoplasm clinical trials from 2000 to 2017 displayed an overall increasing trend, corresponding to 454 unique “neoplastic process” concepts and 3439 unique drug concepts. The number of drug intervention was much greater than the number of the other three interventions.

3.2. Interventional Trend analysis

The number of drug interventions far exceeded other types of intervention. It is notable that the ratio among drug, surgery and radiation interventions kept steady since 2000, whereas the number of other therapies had surpassed surgery and radiation after 2006. The multi-pattern (e.g., combining drugs and surgery) has displayed an increasing trend in years after 2010 as opposed to mono-pattern. Figure 1 illustrates the temporal trend of three drug types including immunologic factors, other bioactive substance and conventional drugs. Conventional drugs outnumbered the rest of drug types but exhibited a decreasing trend and the immunologic factor drugs showed an increasing trend.

Figure 1. The temporal trend of three types of drug

We took breast neoplasm and pancreatic neoplasm as two examples to compare the drug research trends in different types of neoplastic disease. 3,418 breast neoplasm

clinical trials and 1,271 pancreatic neoplasm clinical trials were extracted from our database. The NFs of all experimental drug were calculated in each period and the result for the top popular research drugs were visualized in Figure 2.

Figure 2. NF distribution of the most popular drugs for (a) breast neoplasm and (b) pancreatic neoplasm.

The drugs were ranked by an increasing order of the NFs in the 3rd period. We observed three different drug NF distributions in three periods for breast neoplasm (Figure 2a). As new drugs studies appeared, the peaks of NF distribution dropped and kept moving rightward to these new drugs from 2000 to 2017. The JS distance of drug NF distributions are 12.4 between the 1st and the 2nd period, 20.5 between the 2nd and the 3rd period, and 21.4 between the 1st and the 3rd period. Thus, the drug research focus showed a unidirectional progress trend for breast neoplasm. In contrast to breast neoplasm, the pancreatic neoplasm has significantly different NF distributions as shown in Figure 2b. However, the NF distributions for pancreatic neoplasm among three periods are pretty similar. Over the past three periods, the drug gemcitabine took the lead with a consistent NF for three periods, and is almost thrice as high as the dominant drugs for breast neoplasm, which indicates the relatively limited drug options for pancreatic neoplasm. The JS distance of NF distributions between the 1st and the 3rd period (8.2) is even closer than the distance between the 2nd and the 3rd period (11.8), which implies a reversing research progress trend for pancreatic neoplasm. For breast neoplasm, all popular research drugs have been tested in phase 3/phase 4 clinical trials to gather more information about the effectiveness by studying different populations with different dosages and by using the drug in combination with other drugs.

4. Discussion

The ratio between drug, surgery and radiation has leveled off since 2000, indicating the popularity of research of three intervention types have stabilized, while drug studies are dominating majority in neoplasm trials. Although drug, surgery and radiation remain the major interventions to treat neoplastic disease, the number of other therapies (supportive

care, dietary supplement, behavioral, observation etc.) tested in clinical trials had surpassed surgery and radiation during recent years. This trend reflects the fact that researchers are paying more attention to supportive care and improving quality of life for cancer patients except for radical cure and prolonging OS [2].

The multi-intervention patterns showed an increasing trend after 2010, which is consistent with the popularity of the concept of multimodality therapy in cancer treatment area. The increasing trend of immunologic factor drugs also implies what current drug research focuses on. This trend can be explained by the fact that immunotherapies generally have fewer side effects than chemotherapies because it boosts the body's natural defenses to fight the disease. Most of immunologic factor drugs are referred as monoclonal antibodies. Among them, we recognize several blockbuster drugs such as Avastin, Rituxna, Herception, and Erbitux. These popular cancer treatments target a wide range of conditions and diseases.

We found that neoplastic diseases whose treatment drugs have steadily progressed, like breast neoplasm, present a more even NF distribution and a unidirectional progress trend between distributions. This unidirectional change implies more new drugs introduced into clinical trials that gradually receive more attentions due to their potential of better efficacy. Neoplastic disease whose drug development is stagnant, such as pancreatic neoplasm, present an uneven distribution and a fluctuating trend, implying researchers encountered difficulty developing more effective substitutes for old drugs.

We further integrated diverse data sources to find evidence supporting our findings. For instance, Bevacizumab, a new drug for breast neoplasm, has a peak frequency in 2006-2011, but its frequency drops drastically within the next period. This result can be attributed to the fact that Bevacizumab was once approved by FDA for metastasis breast neoplasm treatment in 2008 but then revoked in 2011 due to safety concerns including severe high blood pressure and hemorrhaging.

5. Conclusions

This study shows interesting trends in the development of interventions for neoplastic disease in clinical trials and interprets the trends with regard to the corresponding medical contexts and literature. It may generate meaningful insight for the cancer research community so that the medical researchers can quantify the progress of cancer research and utilize prior knowledge of trend. The methodology from this study can also be applied to a diversity of medical fields other than neoplastic diseases.

Abstract. Classification systems are widely used in medicine for knowledge representation. The hierarchical relationships between concepts in a classification system can be exploited in prediction models by looking for the optimal predictive granularity level. In this study, we used the Anatomical Therapeutic Chemical (ATC) classification system to cluster medications in the context of predicting medication-related falls in older persons. We compared the performance of fall risk prediction by describing medications at varying granularity levels of the ATC classification system. We found that the level of abstraction significantly affects the predictive performance in terms of both discrimination (measured by the receiver operating characteristic curve AUC-ROC) and calibration. An implication of these findings to the researchers is that data representation at different granularity levels can influence the predictive performance. The optimal granularity level can be determined by experimentation.

Keywords. classification system, data abstraction, feature selection, prediction, granularity, hierarchy.

1. Introduction

Classification systems describe concepts and relationships between them. They are widely used for knowledge representation. The hierarchical relationship between concepts describes the relationship between a class and its sub-class. For example, the Anatomical Therapeutic Chemical (ATC) classification system [1] describes classes in terms of anatomy, therapy, and chemical compounds of medications and generalization-specialization relationships between medications. Hence a medication can be described at various granularity levels. The choice of the appropriate level of abstraction to describe a class (here medication) depends on the task at hand.

When the task is prediction of an event (such as fall of a person), the problem can be stated as: at which level of granularity should medications be described in order to optimize the prediction of that event. This is not a trivial problem, as the error of a

¹ Corresponding Author. Amsterdam UMC, University of Amsterdam, department of Medical Informatics, Amsterdam Public Health Research Institute, Meibergdreef 9, Amsterdam, The Netherlands; E-mail: n.dormosh@amsterdamumc.nl

prediction model is governed by the bias-variance trade off [2]: using a too coarse level of medications to predict falls may lead to parsimonious models with high bias, while using a too detailed level may lead to high variance. This necessitates search within the hierarchy to find the granularity level that leads to the best prediction model. In essence this is a feature selection strategy in prediction models.

Research studies have linked certain medications with an increased risk of falls in what is called fall-risk-increasing drugs (FRIDs) [3]. FRIDs are grouped in fall risk prediction models to ease interpretation [4, 5]. To exemplify the different granularity levels of these medications, consider “paroxetine”, this medication lies on the leaf level of the ATC hierarchy, and is a sub-class of a group called “selective serotonin reuptake inhibitors”. This group has a super-class named “antidepressants” which belongs to the “psychoanaleptics” class and further to the “nervous system” as the main anatomical level. In studies using medication as predictors, the decision on which level of abstraction to use them has often been arbitrary. In addition, little is known about the impact of medication abstraction on fall risk prediction performance.

The aim of this study was to understand the effect of describing medications at different granularity levels on the performance of fall risk prediction. We achieve this by comparing the predictive performance of models using various granularity levels of the ATC classification system.

2. Materials and methods

2.1. Study approach

In this cross-sectional study, we evaluated six prediction models which included the features pertaining to demographics, comorbidity; and home medications. Medications in the dataset are described at ATC level five (leaf level), which can be grouped at different levels of the ATC classification system. We created six prediction models: ATC-5 a model that uses individual medications; ATC-1 to ATC-4 are models that group medications at the respective ATC level; and one model with only demographic and comorbidity features (No-Med).

2.2. Population, patient inclusion and clinical outcome

Data were obtained from the Medical Information Mart for Intensive Care (MIMIC-III, Version 1.4) [6] database. The MIMIC-III is a publicly available database containing de-identified data from more than 40,000 patients admitted to intensive care settings at the Beth Israel Deaconess Medical Center (BIDMC) in Boston, MA, USA, between 2001 and 2012. The dataset comprises demographic elements such as age, gender and ethnicity, clinical elements including vital signs, laboratory data, diagnostic codes (in International Classification of Diseases 9th Edition, Clinical Modification [ICD-9-CM] format) and outcome values. Beside these it contains various types of clinical notes, including discharge summaries and nursing notes.

We included first admissions of older persons (≥ 65 years of age) with complete discharge summaries.

The clinical outcome was falls before hospital admission. Fallers were identified by the presence of an ICD-9 code that starts with “E88” which represent accidental falls, or

the existence of any of the words (fall, fell, fallen) in the text of the reason of hospital admission field.

2.3. Data extraction and processing

The extracted demographic features were age, gender, ethnicity and marital status. We composed an algorithm to extract home medications and comorbidity features from the discharge summaries. The algorithm utilized RxNorm [7] and the Systematized Nomenclature of Medicine Clinical Terms (SNOMED CT) in order to match the medications and the comorbidities in the text. Data processing involved the mapping of the extracted medications into ATC codes (level five) using the Observational Health Data Sciences and Informatics (OHDSI) [8] and obtaining all the super (parent) groups for each medication code.

2.4. Statistical analysis

We used the Least Absolute Shrinkage and Selection Operator (LASSO) with logistic regression to allow for feature selection as part of fitting the model and to avoid overfitting [9]. LASSO trades off an increase in bias with a decrease in variance, by adding a penalty against model complexity. This penalty term (λ) is usually chosen by cross-validation. The analysis was performed using the R programming language, version 3.4 and data extraction was performed using Python. We used the implementation in the R *glmnet* package to perform LASSO regression.

We assessed the performance of the models in terms of discrimination (with the area under the receiver operating characteristic curve: AUC-ROC); calibration via calibration plots; and the relative goodness of fit with the Akaike Information Criterion (AIC). To internally validate the results, we applied bootstrapping [10] with 200 recommended repetitions and we calculated the optimism-corrected AUC-ROC. To get an honest assessment and to address LASSO instability of model performance all modelling steps (λ -tuning) were repeated for each bootstrap sample. To test for statistical significance of the differences in the median between each of the models and the model with medications without grouping (ATC-5), we used Wilcoxon signed-rank test. A p -value < 0.05 was considered to indicate statistical significance.

3. Results

The total number of patients was 46,520 in the MIMIC-III database. The number of patients which met the inclusion criteria was 23,034 (49.5%). The number of fallers was 1,721 (7.5% of the included patients). The number of different medications extracted from the discharge summaries was 939.

Figure 1 depicts the relationship between the AUC-ROC and the level of ATC grouping. It can be seen that the AUC-ROC initially increases when climbing up the hierarchy of the ATC, peaks at level two and then drops at the first level of the ATC.

The calibration performance of the models is shown in Figure 2. All the models showed acceptable calibration except the No-Med and ATC-4 models which had miscalibration. As shown in Table 1, the lowest AIC estimate (lower is better) was for the model ATC-2 followed by the model ATC-3. The number of selected features for these two models were 65 and 110 respectively.

Figure 1. The relationship of AUC-ROC with different levels of grouping using the ATC. Note that the y-axis does not start from zero.

Figure 2. Bootstrap bias-corrected calibration curves of the models.

Table 1. Akaike Information Criterion and the number of selected features after applying LASSO regression.

Models	AIC	#Total Features	#Selected Features
No-Med	-16,406.67	38	28
ATC-1	-16,615.84	52	37
ATC-2	-16,838.66	118	65
ATC-3	-16,655.52	212	110
ATC-4	-16,444.1	465	121
ATC-5	-16,369.3	977	196

4. Discussion and conclusion

This study investigated the effect of leveraging hierarchical relationships of concepts in classification systems for predictive modelling. Our experiments indicate that significant improvement in predictive performance can be achieved by altering granularity levels. This is demonstrated by the ATC-2 model having the highest discrimination performance, acceptable calibration and the lowest AIC.

The strengths of our approach include a systematic evaluation of the performance of the prediction models and the use of bootstrapping to validate the results. The main limitation lies in the fact that the ICD-9 codes were generated for billing purposes at the end of the hospital stay and may not always represent falls before admission. Although the inspection of a random sample of the discharge summaries revealed that most of the patients fell before admission, there still is uncertainty in the definition of fall and the exact moment of its occurrence. This limitation may have affected the overall estimation of falls risk and prediction performance because we considered only home medications

registered on admission and not during hospital stay. Furthermore, we could not validate the accuracy of the algorithms used to extract medications on admissions and comorbidities because of the lack of an annotated dataset. We however, believe these limitations should not qualitatively affect our findings as we evaluated the models under the same conditions.

The utilization of granularity in classification systems was also investigated in other domains. A recent study evaluated the impact of altering bacterial taxonomy on disease prediction [11]. The authors found that describing bacteria at different granularity levels influenced the predictive performance. This finding corroborates what we observed in this work. Another recent study evaluated how different levels of data granularity of medications and diagnoses would affect prediction of diabetic kidney disease (DKD) prediction [12]. The authors showed that different data granularity may not necessarily influence the predictive performance. However, this differs from the findings presented here and this discrepancy could be attributed to the differences in the domains on which the approach was evaluated.

On the basis of this work, we conclude that describing features at different levels of granularity can significantly affect the predictive performance. So far, we considered the same level of granularity to describe medications. A possible interesting extension to our work is to apply tree-lasso [13] or a (greedy-based) search strategy to select a subset of nodes in the tree-structured medication hierarchy. Another important work that warrants further investigation is validating our results on another dataset. Our findings have implications for researchers: we showed that prediction performance can be enhanced by altering the granularity of the data, and the optimal level of granularity can be obtained by experimentation.

Incorporation of Multiple Sources into IT - and Data Protection Concepts: Lessons Learned from the FARKOR Project

Doris LINDOERFER^{a,1}, Ulrich MANSMANN^a and Isabel REINHARDT^{a,b}

^a *Institute for medical Information Processing, Biometry and Epidemiology, Ludwig-Maximilians-Universität München, Munich, Germany*

^b *Medical center of the university of Munich*

Abstract. The IT- and data protection concept of the FAmiliäres Risiko für das KoloRektale Karzinom (FARKOR) project will be presented. FARKOR is a risk adapted screening-project in Bavaria, Germany focusing on young adults with familial colorectal cancer (CRC). For each participant, data from different sources have to be integrated: Treatment records centrally administered by the resident doctors association (KVB), data from health insurance companies (HIC), and patient reported lifestyle data. Patient privacy rights must be observed. Record Linkage is performed by a central independent trust center. Data are decrypted, integrated and analyzed in a secure part of the scientific evaluation center with no connection to the internet (SECSP). The presented concept guarantees participants privacy through different identifiers, separation of responsibilities, data pseudonymization, public-private key encryption of medical data and encrypted data transfer.

Keywords. Data integration, HIC data, pseudonymization, data encryption

1. Introduction

The *FAmiliäres Risiko für das KoloRektale Karzinom* (FARKOR) project assesses the efficacy and safety of a risk adapted screening-program focusing on familial colorectal cancer (CRC) in young adults (aged 25-50 years of age) [1]. It is implemented in Bavaria, Germany [2]. The project integrates individual data from different sources: (1) individual diagnostic and treatment data from medical practitioners, (2) individual patient-reported lifestyle data, and (3) individual outcome data from health insurance companies (HIC).

FARKOR has two parts: (1) Efficient selection of persons with familial colorectal cancer risk within a population of 3 million people, (2) offering safe and efficient screening approaches for the selected high risk population. FARKOR is a prospective, population-based cohort study. Its efficiency is assessed by (1) the number of advanced adenoma or carcinoma detected in the selected high-risk population, (2) a health economic evaluation that estimates avoided morbidity and mortality.

A large number of practices enrolled into the project. All 35 health insurance companies working within Bavaria participate. They provide individual outcome data

¹ Corresponding Author: Doris Lindoerfer, lindoerf@ibe.med.uni-muenchen.

regarding CRC mortality and morbidity. This allows to have control outcome of persons not enrolled in FARKOR.

To implement and to run this project successfully, a reliable IT infrastructure and robust data protection concept has to be established that is also compliant with the new European General Data Protection Regulation (EU-GDPR) [3].

2. Methods

2.1. Several institutions and responsibilities

The FARKOR project integrates data from multiple sources and exchanges the data between different institutions (see Figure 1).

2.2. Specific challenges and used methods

Specific challenges regarding the data protection concept are: 1.) Integrating data from different sources; 2.) Protecting the privacy of participating individuals 3.) Protect business issues between the participating HICs (which patient is insured by which HIC); 4.) Providing the legal reasons for collecting the data (informed consent for subjects enrolled in FARKOR, permission to use individual data of persons not enrolled in FARKOR – the controls); 5.) Performing person rights: Informing about collected data or deleting the records on request; 6.) Providing a 24/7 availability of the IT-infrastructure.

The FARKOR IT- and data protection concept is built on several strategies [4-10]: Informational separation of powers (Informationelle Gewaltenteilung [11]) by using different identifiers for data of different origin [4]; Pseudonymization of identifiers [5] and encryption of personal health information [6]; a trust center [7] and concepts of asymmetric encryption and pseudonymization [8-10].

Integration of HIC data over multiple databases uses standardized terminologies like the International Classification of Diseases, 10th Revision (ICD-10), *Operationen- und Prozedurenschlüssel* (OPS) and *Einheitlicher Bewertungs Maßstab* (EBM).

3. Results

3.1. IT- and data protection concept with data flow

The program started in October 2018. By end of December 2019 about 9000 persons were enrolled. The data capturing, data encryption, data flow (see Figure 1), pseudonymization and data decryption work appropriately.

A specific data service by the resident doctor's association (1) *KVB data service* administrates the individual project data. It is separated from the institution's routine data and general activities. The (2) *trust center* pseudonymizes the data identifiers.

The *KVB data service* provides an internet portal to document the *medical data*: demographic, diagnostic, and treatment data of individuals enrolled in FARKOR. After informed consent, participants are enrolled by their primary care physician who does a basic familial CRC risk assessment. In case of a positive assessment, the participant

will be referred to specialists for further staging and potential screening measures. The *KVB data service* encrypts the data and makes it available to the trust center for download.

Record linkage between the *medical data* and the individual health insurance data uses the social security numbers (KVNR). The trust center downloads the medical data from the *KVB data service*, removes the specific HIC IDs, pseudonymizes the individual IDs, and makes the data available for download to the secure evaluation environment (SECSP). The SECSP is a secure part in the secure evaluation center (SEC) with no connection to the internet.

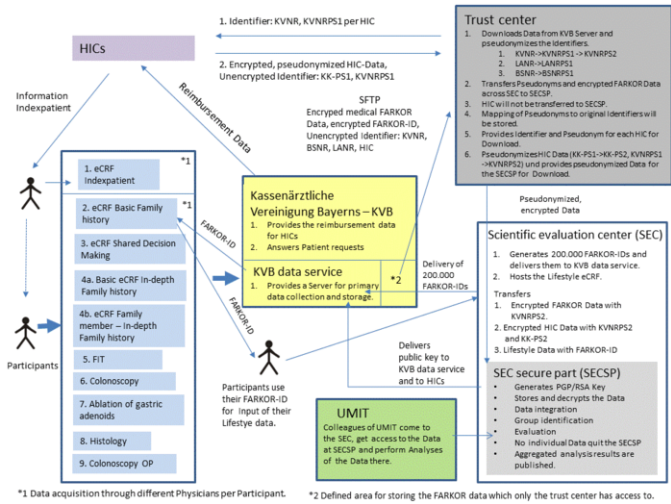

Figure 1. Data flow in the FARKOR project.

The trust center provides at scheduled points in time, the social security numbers (KVNR) and a pseudonym of the KVNR of the FARKOR participants to the HICs for download. The HICs match individual data with related ICD-10, OPS and EBM codes according to the specified identifiers. The HICs pseudonymize the data accordingly, remove the KVNR and deliver the pseudonymized data back to the trust center. The trust center pseudonymizes the HIC data, performs the record linkage and allows to download the data to the SECSP. The HICs data is now doubly pseudonymized.

The concept of informational separation of powers requests, that all medical data is encrypted by the KVB data service and has to be decrypted in the SECSP. Encryption uses public-private-key RSA encryption. Patient-related data are encrypted with the public key. The identifying variables are not encrypted for pseudonymization purposes. It was requested by the LMU's IRB that the trust center cannot read the medial data.

The SECSP downloads the data and decrypts the individual medical data with the private key. Then the SEC performs data storage, data integration and analysis. All data transfers are transport-encrypted.

Furthermore, lifestyle data are important for the analysis. The SEC created individual FARKOR-IDs, which are delivered to the *KVB data service*. These IDs are provided to the participants when they enroll and allows login to the lifestyle questionnaire website. Participants use their internet browser to answer the lifestyle

questionnaire. The corresponding server is hosted in the SEC. These data will be transferred to the SECSP and integrated to the project data with the FARKOR-ID.

The health economic evaluation is carried out by partners at the Private University for Health Sciences, Medical Informatics and Technology (UMIT). They perform their analysis within the SEC. No data leaves the SECSP.

3.2. Warranty of the participants rights

Participants may request at any time a copy of their individual data stored. They can also withdraw their consent of participation in FARKOR at any time. Their requests are handled in a standardized manner. The process for withdrawal is shown in Figure 2. To date, four participants have withdrawn their consent. The corresponding data was deleted from the analysis data. So far, no participant has requested access to their data records.

Figure 2. Data flow when participants withdraw their consent.

4. Discussion

The FARKOR IT- and data protection concept enables the integration of multi-source data. To our knowledge, this paper describes for the first time an EU-GDPR conform simultaneous integration of individual HIC as well as project data during the course of the study. The integration of HIC data allows to have control groups of persons not enrolled in FARKOR, as well as data for subjects enrolled that supplements data documented during medical examinations. This makes it necessary to collect and store social security numbers (KVN). This record linkage process is complex. The KVN is stored and pseudonymized in the trust center and communicated to the HICs. The KVN is not transmitted to the SECSP. The medical data will be encrypted in the KVB data service and decrypted in the SECSP. The medical data and the FARKOR-ID are only available in encrypted form to the trust center.

5. Conclusion

To integrate the multi-source data, a strong IT infrastructure as well as an appropriate data protection concept is needed to guarantee participating persons privacy. This is achieved by using different identifiers for data of different origin, pseudonymization of identifiers in a trust center, encrypted data transfer and encryption of patient-related data.

Ethics and approval

The Institutional Review Board (IRB) of the Medical Faculty of the Ludwig-Maximilians Universität München, Munich, Germany has given ethics approval for this study (18-545). The FARKOR data protection concept has been approved by the Bavarian State Data Protection Commissioner. Furthermore, it was approved by the supervisory authorities of the HICs, the Bavarian State Ministry of Health and Nursing and the Federal Insurance Office, this was necessary because also data about persons not participating in FARKOR are provided by the HICs. The FARKOR IT- and data protection concept was also presented and discussed in the (TMF) e.V. [11], working group data protection (AG DS).

Integrating the Comparative Toxicogenomic Database in a Human Pharmacogenomic Resource

François-Élie CALVIER ^{a,1}, Cedric BOUSQUET ^{a,b}

^aPublic Health and Medical Information Unit, University Hospital of Saint Étienne, Saint Étienne, France

^bSorbonne Université, Inserm, université Paris 13, LIMICS, Paris, France

Abstract. Information relevant to pharmacogenomics studies is available in several open databases, which makes it difficult to synthesize the available data. Within the PractikPharma project, several databases were integrated to PGxLOD, a resource dedicated to the generation and verification of pharmacogenomic influence on drug responses. The Comparative Toxicogenomic Database (CTD) describes the toxic effects of many chemicals on living species based on the literature. Since drugs are peculiar chemicals and side effects are peculiar toxic effects, we aimed at extracting information from CTD that matches drug side effects in the human specie.

Keywords. Pharmacogenomics, biomedical genomics, Data interoperability and data integration, Quality of data,

1. Introduction

Pharmacogenomics is a branch of pharmacology that studies how drug responses may be influenced by the genome. As information relevant to discovering and explaining such responses are available in several databases, the consortium of the PractikPharma project implemented methods to extract state of the art knowledge from these databases and the literature. First, PGxO [1], an ontology covering the pharmacogenomic domain was proposed, which focuses on human and drug relative information. Second, this model was implemented in PGxLOD, a pharmacogenomic LOD i.e. a semantic entry (a SPARQL endpoint) to access and query pharmacogenomic data.

The Comparative Toxicogenomic Database (CTD) [2] is a premier public resource for literature-based, manually curated associations between chemicals, gene products, phenotypes, diseases, pathways and environmental exposures. Considering drug as particular chemicals and pharmacogenomic relations as particular toxicogenomic relations, we identified CTD as a potentially interesting pharmacogenomic information resource. In this paper, we describe the method applied to extract data relevant to pharmacogenomic studies from CTD to prepare its integration to PGxLOD.

¹Corresponding Author: François-Élie Calvier, CIM 42, chemin de la marandière, CHU de Saint-étienne Hôpital Nord 42055 SAINT-ÉTIENNE CEDEX 2, France; E-mail: francois.calvier@chu-st-etienne.fr

2. Material and Method

We first describe CTD data. Then, we explain how we selected and extracted data from CTD. Finally, we integrated these data to PGxLOD by mapping elements from the same classes that were previously imported in PGxLOD from other databases.

2.1 Data representation in CTD

CTD provides a collection of biological links documenting toxicogenomic connections. An initial set of links is gathered through a semi-automatic systematic review of pubmed articles. This task consists first, in identifying the elements (i.e. chemicals, genes or diseases) involved in those links. Then, in associating a link with the pubmed IDs of the articles that mention co-occurring elements. Links validated by CTD curators are annotated using controlled vocabularies. In a latter step, these links are integrated with data from external reference databases. For example, chemicals are mapped to the Chemical Abstract Service (CAS) [3], Medical Subjects Headings (MeSH) [4], and DrugBank [5] databases. Genes are mapped to the NCBI gene database [6]. Diseases are mapped to the MeSH, and pathways are mapped to Kyoto Encyclopedia of Genes and Genomes (KEGG) [7] and Reactome [8] databases. Finally, additional links are inferred by reasoning over the curated set of links.

Regularly updated, 164,640 chemicals, 470,706 genes, 12,784 diseases, and 2,363 pathways over several species and their known biological links were represented in 2017 (version 14932). Biological links represented in CTD can be either documented knowledge from the literature or inferred knowledge. We detail these links in table 1. When links are inferred, the inference node is specified in parenthesis.

Table 1. Biological links statistics

	Chemicals	Genes	Diseases
Genes	1,482,537	—	—
Diseases	5,245,672	62,519,080	—
Direct evidence	94,065	29,715	
Inferred	5,151,607 (Genes)	62,489,365 (Chemical)	
Pathways	1,119,270	135,816	544,767
Direct evidence	1,119,270	135,816	0
Inferred	0	0	544,767 (Genes)

2.2 Data extraction from CTD

In order to extract human pharmacogenomic data from CTD, drugs should be distinguished from other chemicals, and human genes should be distinguished from genes belonging to others species. We filtered biological links in order to discard those involving non-human genes and non-drug chemicals. Finally, we removed pathways and diseases

without a biological link involving a drug or a human gene. Identification of Drugs was the main difficulty of the extraction process.

Chemicals are described in CTD by their names, and some external databases IDs. These external IDs, in particular DrugBank ID and CAS RN, were exploited to identify drugs among the chemicals. As DrugBank is a drug database, a chemical in CTD with a DrugBank ID is necessarily a drug. The CAS number is a unique identifier defined by the American Chemistry Society (ACS). It is widely used in several databases, and can be found in DrugBank and in KEGG.

2.3 Direct Exploitation

56,536 chemicals in CTD have a non empty CAS number field which is available for 4,789 drugs in DrugBank. This information is also available for 8,760 within the 10,467 drugs present in KEGG. An identification of chemicals which are actually drugs was performed using the CAS number as a pivot.

2.4 Indirect Exploitation

Several databases relative to drugs do not mention the CAS number. Moreover, this information is often incomplete like in DrugBank and KEGG. Therefore, we also exploited the Pharmacogenomics database (PharmGKB) [9] as a reference drug database. KEGG and PharmGKB provide more cross-references than DrugBank (resp. 5 and 19), that can be exploited thanks to web services to reinforce mappings using the CAS number:

- Unichem [10] provides mappings between 38 databases including CAS but was not updated since 2014.
- Chemical Identifier Resolver (CIR) [11] is a NIH web service that includes mappings between CAS, InChI, and chemSpider identifiers.

2.5 Integration of selected data from CTD to PGxLOD

Many databases for life sciences already have been integrated in the Bio2RDF project [12]. Several databases (e.g. DrugBank, KEGG, and PharmGKB) have been integrated to PGxLOD thanks to a mapping between their respective ontologies. Nevertheless, as Bio2RDF has not been updated since 2014, we integrated CTD data to PGxLOD by using a script written by following the Bio2RDF guidelines.

3. Results

3.1 Extraction Results

4,944 drugs were identified within CTD chemicals. DrugBank IDs of 1,710 chemicals are available in CTD which makes identification straightforward for these chemicals. Thanks to the CAS number as a common foreign key 4,363 drugs were identified among CTD chemicals (resp. 1,235 from DrugBank and 3,328 from KEGG). 1,731 of the drugs from KEGG were not identified thanks to DrugBank. Finally, Exploiting web services lead to the identification of 268 additional drugs. From the identified drugs, it is possible to extract biological links that are relevant for human pharmacogenomics. We provide, in

table 2, the number of extracted links with respect to CTD existing links. A gene is involved in a relation with a drug if there is a relation with a chemical from CTD that has been identified as a drug. Thus, 31,559 genes are involved in the 631,143 drug-gene links. Moreover, 19,780 genes of this subset belong to the human genome.

Following the same rule, diseases and pathways relevant to human pharmacogenomics are extracted. The respective numbers are shown in table 3.

Table 2. Extracted Biological links statistics

	CTD	Human pharmacogenomics
Chemical-Gene	1,482,537	631,143
Chemical-Disease	94,065	5,388
Chemical-Pathways	1,119,270	235,430

Table 3. Extracted linked elements

	CTD	Human pharmacogenomics
Chemicals	164,640	4,944
Genes	47,706	19,780
Diseases	12,784	6,796
Pathway	2,363	2,061

3.2 Integrating CTD Data to PGxLOD

Even if all extracted biological links are relevant to human pharmacogenomics, we have chosen to integrate to PGxLOD only those that were manually curated. Since PGxLOD is a semantic resource, all inferred links from CTD could be retrieved by adding an inference rule when using a reasoner. We represented Biological links as objects in order to keep the documentation link information. Thus, a biological link between two biological elements was represented by two properties between each element and the biological link object. Pubmed ID was then added as a property of a biological link in PGxLOD.

4. Discussion

We conducted the extraction of data relevant to pharmacogenomics studies from CTD. This extraction was first expected as an easy task because of the existence of cross references between CTD and DrugBank. But, later, we realised there was a lack of interoperability between data provided by the chemistry and biomedical communities, and that most of the cross references were missing (less than 10% of the DrugBank drug IDs are found in CTD and the CAS RN information is available for less than 50% of DrugBank drugs). Our extraction task is complete with respect to the limitations of our approach.

The integration of CTD in PGxLOD lead to an update of PGxO. Since biological links were relations between two elements and PGxO expects ternary relations, we represented links as an object property in PGxO. CTD enables the possibility to provide the literature link referencing a biological link evidence. To take advantage of this resource, biological links should be represented as a concept with the linked biological elements and the literature references as properties.

Our approach is mainly manual and requires much time to understand chemical and biomedical knowledge. The gap between both communities obstruct our reconciling efforts. Moreover, many database cross-references are out-dating and can lead to uncertain results. Nevertheless, the CTD project is still providing updates and particularly CAS number information for more and more chemicals. As only a third of CTD chemicals were studied in our extraction due to CAS number availability, the process can be

reproduced to improve the extraction with the updated data. Finally, we chose to exploit only invariable information such as IDs to perform an automatic extraction. Information like the name of the chemicals could also be exploited in a semi-automatic process.

Thanks to the integration of CTD to PGxLOD, experiments could be conducted to explore the link between adverse drug reactions and molecular characteristics of the drugs [13].

Integration of Unstructured Data into a Clinical Data Warehouse for Kidney Transplant Screening -Challenges & Solutions

Maximilian ZUBKE^{a,1}, Matthias KATZENSTEINER^a and Oliver J. BOTT^a

^a*University of Applied Sciences Hannover, Hannover, Germany*

Abstract. After kidney transplantation graft rejection must be prevented. Therefore, a multitude of parameters of the patient is observed pre- and postoperatively. To support this process, the Screen Reject research project is developing a data warehouse optimized for kidney rejection diagnostics. In the course of this project it was discovered that important information are only available in form of free texts instead of structured data and can therefore not be processed by standard ETL tools, which is necessary to establish a digital expert system for rejection diagnostics. Due to this reason, data integration has been improved by a combination of methods from natural language processing and methods from image processing. Based on state-of-the-art data warehousing technologies (Microsoft SSIS), a generic data integration tool has been developed. The tool was evaluated by extracting Banff-classification from 218 pathology reports and extracting HLA mismatches from about 1700 PDF files, both written in german language.

Keywords. NLP, image processing, information extraction, data warehouse, graft rejection, kidney transplant

1. Introduction

Due to demographic change an increasing number of severe kidney disease cases and, as a result, an increasing need for kidney transplants can be expected. Early detection of graft rejection is therefore of particular importance in the therapy of kidney transplanted patients.

The joint project "Screen-Reject: A lateral flow test for rejection diagnostics" focuses on innovative diagnostics for the aforementioned purpose and is stratified into three subprojects. The subproject "Screen-Reject: Clinical data warehouse for graft rejection diagnostics" of the project network is concerned with the provision of a clinical data warehouse (CDWH) as a starting point for the development of an expert system to support rejection diagnostics based on clinical data. [1]

In the course of the medical monitoring of patients, both structured treatment-relevant data and unstructured findings texts are recorded. These unstructured findings texts pose special challenges for data extraction.

¹ Corresponding Author, Maximilian Zubke, University of Applied Sciences Hannover, Expo Plaza 12, 30539 Hannover, Germany; E-Mail: Maximilian.zubke@hs-hannover.de.

1.1. Requirements of clinical practitioners and scientists

Our clinical partners are especially interested on the Banff classification [2,3] as well as several information from examinations of human leukocyte antigens (HLA). A requirement analysis resulted in the following four requirements for the CDWH:

- Obtaining the distribution of Banff classification for all the patients included in our study.
- Selecting patients by Banff classification and coding results.
- Estimating the most common HLA mismatches.
- Selecting donor/receiver pairs having certain HLA mismatches.

However, since that information are only described in narrative instead of structured reports, it is not yet possible to select certain variables and filter them by value.

Thus methods are needed to extract the relevant information from the narrative reports.

2. Method

2.1. Data Staging

Initially, reports from the local pathology lab and the clinic for transfusion medicine were acquired. While the pathology reports could be provided as plaintext block from another clinical data warehouse [4], the findings from transfusion medicine were only available as PDF files. Thus the data staging environment have been extended by a data lake. Any information that could not be imported directly into the data warehouse was temporarily stored in the data lake.

2.2. Extracting Banff classification from staged plaintext blocks

The extraction, transformation and loading of defined information from narrative plaintext was realized by a SSIS² package. This package requires a source table containing plaintext resp. file paths to text data and processes the rows sequentially by a JSON-based communication with external text mining functionality. In detail, one or several external text mining tools can be connected with the SSIS package by corresponding script tasks. Finally, the data provided by the script task is written to previous designed tables of the data warehouse. Figure 1 illustrates this workaround.

² SQL Server Integration Services (<https://docs.microsoft.com/en-us/sql/integration-services/sql-server-integration-services?view=sql-server-ver15>)

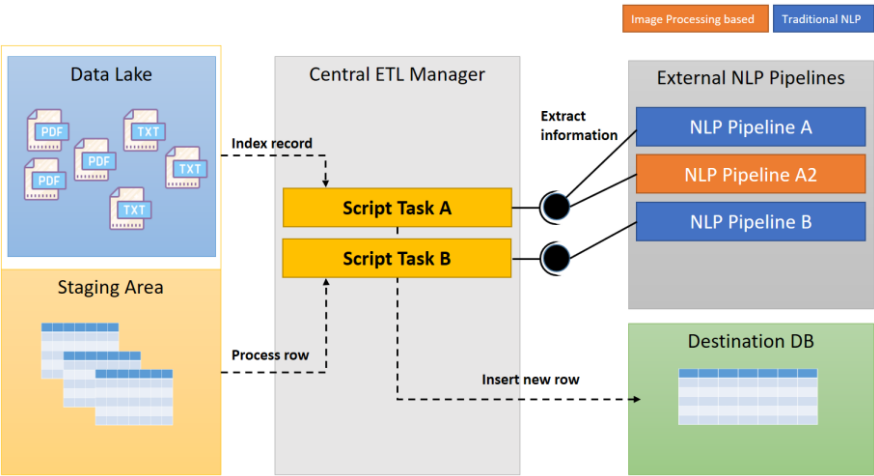

Figure 1. Workflow of the SSIS based ETL package: A central component coordinates the data flow and communicates with external NLP Pipelines via corresponding SSIS Script Tasks.

In the present case, the determined Banff categories [2,3] including optional comments as well as the Banff coding [2,3] should be extracted from pathology reports.

Considering that, two script tasks have been created, getting the same input but interacting with different NLP pipelines (one for each information to be extracted) and sending the output to two different tables in the destination database. The NLP pipelines can be any executable program which generates structured JSON output that is interpretable by the corresponding script task. In our use case, all NLP pipelines were represented by compiled python3 scripts. The information extraction functionality was realized using regular expressions.

2.3. Reverse engineering of HLA mismatch table from unstructured PDF files

In contrast to pathology findings, reports about HLA mismatches could not be made available in form of plaintext blocks, provided by another data warehouse. Instead, the only available descriptions were PDF files generated by third-party software or a scanner.

For this reason, the first step was the transformation of PDF files to text files. A preprocessing step that converts each PDF file to a text file without losing information like headlines or line breaks has been integrated. However, this approach was not able to recognize tables: Visual lines that separate rows and columns were not extracted and thus the whole table was transformed to a text block, whereby internal borders between rows and columns as well as external borders to previous and following document content. Even conversions to Word Documents or other formats failed in most cases. However, from a visual perspective, tables are obvious and clearly delimitable parts of a document. Due to this, we decided to read the table of mismatches by image processing instead of natural language processing. Therefore, the PDF is considered as an image and the first step of this approach is the detection of horizontal and vertical lines [5]. Next, intersections of these lines are calculated. Thereafter, reading the document from left to right, each recognized intersection marks the border between columns and horizontal lines having intersection with the same vertical lines mark the rows.

Figure 2. Sample image of a HLA table: Cell values are antigen stereotypes that extend the HLA name in the headline of the same column. Each row describes a sample from a patient.

Finally, the image regions surrounded by the intersection points become extracted and analyzed by an OCR component, OCR errors are prevented by comparing the results with the plaintext of the PDF. Geometric coordinates about the position of lines and intersection points are used to associate regions with each other and deriving the semantic information; For example, in Figure 2 the cell containing “HLA-A” and the cell containing “*02,*03” are surrounded by the same vertical lines and located in the same geometric region on Y-axis. Image regions having the same coordinates on the X-axis are interpreted as fields of the same row.

Overall, using visual features instead of linguistic or keyword based approaches, works fine to recognize the semantic structure of a mismatch table within a PDF-based report.

The extraction of the remaining content of interest, which is represented as a section or list is done by the same approach as described in section 2.2.

3. Result

As illustrated in Figure 3, the requirements mentioned in the introduction were fulfilled by extending ETL-pipelines with methods from natural language processing and image processing.

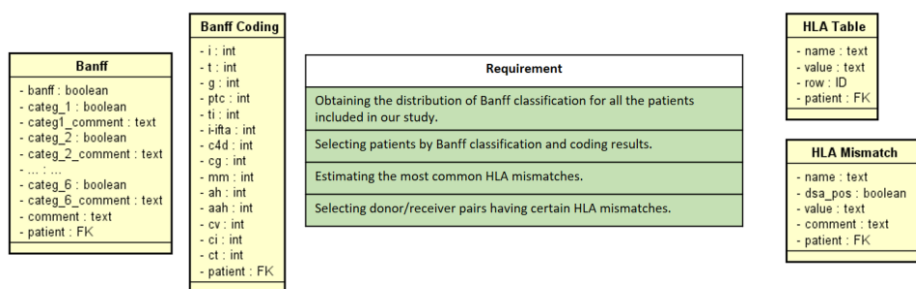

Figure 3. Requirements (green) were fulfilled by providing detailed information tables (yellow).

Technically, the described process was implemented by a generic SSIS package, which can be reused for further, similar data integration projects.

3.1. Evaluation

The described data integration approach was used for 218 pathology reports and 1700 HLA reports, both in German, given by the source dataset provided for this research project.

The correctness of our ETL approach was checked by manual verification of the mapping results. Our approach reaches a precision of 100% and a recall of 100% for pathology reports and 85% for the HLA reports. The latter recall of only 85% has been caused by unexpected document structures. After appropriate modifications, also the NLP Pipeline for the HLA reports reached a recall of 100% and finally all requirements were accomplished.

4. Conclusions

Even this work has confirmed that clinicians tend to document crucial information in form of free texts. Thus, clinical information systems shall be able to extract information of interest from such documentations and transform it into structured representations required for secondary use in research and care. The transformation of information from free text to structured formats is typically done using natural language processing. However, it has been shown, that methods from image processing can outperform traditional NLP in some specific tasks like the extraction of coherent document parts which are marked visually like e.g. tables.

5. Acknowledgement

We want to thank the center for information management of the hanover medical school for providing servers and enabling a connection to their clinical data warehouse.

The research for this paper was done within the joint project “Screen Reject”, founded by the European Regional Development Fund (ERDF) and the State of Lower Saxony, Germany.

Abstract. We propose mini-batch top-n k-medoids to sequential pattern mining to improve CGM interpretation. Medical workers can treat specific patient groups better by understanding the time series variation of blood glucose results. For 10 years, continuous glucose monitoring (CGM) has provided time-series data of blood glucose thanks to the invention of devices with low measurement errors. We conducted two experiments. In the first experiment, we evaluated the proposed method with a manually created dataset and confirmed that the method provides more accurate patterns than other clustering methods. In the second experiment, we applied the proposed method to a CGM dataset consisting of real data from 163 patients. We created two labels based on blood glucose (BG) statistics and found patterns that correlated with a specific label in each case.

Keywords. continuous glucose monitoring, subsequence time-series clustering

1. Introduction

In this paper we propose an interpretation method for extracting characteristic sequential patterns from given pairs of labels and continuous glucose monitoring (CGM) value sequences, facilitating better interpretation of CGM values. The label shows a patient's state such as blood glucose level. The key technology is mini-batch top-n k-medoids that provides accurate cluster centers. By clustering the data, we group similar elements of data to find patterns more effectively.

Device makers provide analysis software for CGM logs². The International Diabetes Center created an analysis schema, the "Ambulatory Glucose Profile," consisting of more than 10 metrics, including mean glucose [1]. This analysis schema handles one patient's CGM logs and does not compare them with other patient's logs. We provide sophisticated scheme for comparing patient's logs.

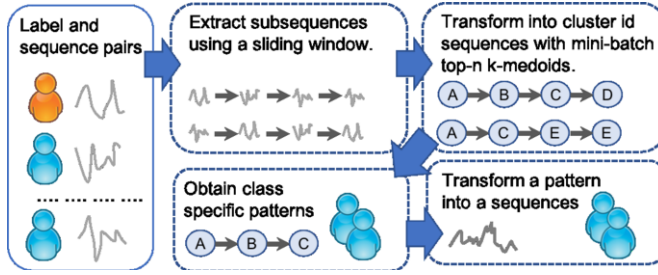

Figure 1. Overview of proposed interpretation method: In this case, the two labels are orange or blue. Our interpretation method extracts the pattern that highly correlates with the blue label.

Medical service workers have to understand patient lifestyles to determine a therapeutic strategy. Thanks to technological advancements in medical devices, we can measure glucose by the minute for weeks using CGM. CGM provides time-series data and has been available since devices with low measurement errors appeared 10 years ago. The review study about CGM [2] reported that there is an urgent need for a standardized interpretation of glucose data and patterns akin to automated electrocardiogram interpretation.

We conducted two experiments, one with a manually created dataset and one with a dataset consisting of actual CGM data. In the first experiment, we evaluated mini-batch top-n k-medoids and determined if our method outperforms other related methods. In the second experiment, we applied our interpretation method to a CGM dataset, that is created through clinical trials, containing 223 waves from 163 real patients over a 2-week period. We extracted interesting patterns from the CGM dataset.

2. Methodology

Our interpretation method consists of the four steps shown in Figure 1. First, we extract subsequences from given sequences by using a sliding window. Next, we apply mini-batch top-n k-medoids to transform CGM value sequences into cluster ID sequences. By clustering the data, we group similar elements of data to reduce noise. Then, we apply sequential pattern mining to extract sequential patterns that correlate with a specific label. Finally, we interpret a label-specific pattern by replacing a cluster ID with a cluster center sequence and obtaining a CGM value sequence.

The procedure of mini-batch top-n k-medoids basically follows the partitional clustering method, but the novel extension uses a mini-batch and n centers in one cluster and runs faster with large-scale data while maintaining clustering accuracy. Some studies have reported that k-means with an Euclidean distance metric for subsequence time-series clustering is useless because the cluster centers are similar to a sine wave [3][4], which is unfavorable to our interpretation task. To address this issue, we use a k-medoid-based method that can use any distance metric and does not create cluster centers based on the Euclidean space.

Let \mathbf{X} denote a set of elements in \mathbf{R}^d and \mathbf{dist} denote a function that returns the distance between two elements. Let \mathbf{C} denote a set of cluster centers and $\mathbf{C}^{(i)}$ denote centers in i -th cluster. Let n denote the number of centers in a cluster, and k denote the number of clusters that is predefined. The method finds a set of cluster centers $\mathbf{C}^{(i)}$ in

$\mathbf{R}^{n \times d}$ that minimize the loss $\emptyset(\mathbf{X}, \mathbf{C}) = \sum_{x \in \mathbf{X}} \min_{i=1}^k \frac{1}{n} \sum_{y \in \mathbf{C}^i} \text{dist}(x, y)$. To minimize the loss \emptyset , we repeatedly update a set of cluster centers \mathbf{C} and each cluster element based on mini-batch $\mathbf{X}' \subseteq \mathbf{X}$ and the following loss functions $\emptyset(x, \mathbf{C}^{(i)}) = \frac{1}{n} \sum_{y \in \mathbf{C}^i} \text{dist}(x, y)$ and $\emptyset(x, \mathbf{X}') = \frac{1}{|\mathbf{X}'|} \sum_{y \in \mathbf{X}'} \text{dist}(x, y)$. When we determine a cluster of $x \in \mathbf{X}'$, we select cluster centers $\mathbf{C}^{(i)}$ that minimizes the loss \emptyset_x , which is the sum of the distance between x and $\mathbf{C}^{(i)}$. When we assign the i -th cluster's centers, we sort the i -th cluster's elements in ascending order based on the loss \emptyset_c , the averaged distance to the elements in the same cluster, and select the top- n elements. At the end of each iteration, we calculate the loss \emptyset to determine whether the loss \emptyset is converged. If the loss is converged, we stop the iteration. Otherwise, we randomly update mini-batch \mathbf{X}' and start the next iteration.

3. Experimental Results

Experiment with the manually created dataset: We created a dataset that contains 500 waves with 16 dimensional attributes. Since the real data has no clear definition for cluster centers, we evaluate our method on the basis of the manually created dataset. First, we created four base waves \mathbf{B} with four dimensions. An element of a wave is a random integer in the half-open interval $[0, 20)$. Second, we created one wave \mathbf{W} by randomly combining the four base waves and multiplying a noise. Let $\mathbf{w}^i \in \mathbf{W}$ and $g \sim \mathcal{N}(\mu = 1.0, \sigma^2 = 0.15)$ be i -th value of the wave and the noise, respectively. Then we define the value with the noise as $\mathbf{w}_i \cdot g$. Finally, by repeating the previous steps, we created a dataset with 500 waves.

We evaluated the clustering performance by measuring the average Earth Mover's Distance (EMD) between the four base waves and the cluster centers. EMD is a distance metric designed to handle time-series data, and lower average EMD indicates a better clustering performance. Let \mathbf{C} be the cluster centers. Let emd be the function that returns the EMD between a pair of waves. The criterion is formulated as $\sum_{b \in \mathbf{B}} \min_{c \in \mathbf{C}} \text{emd}(b, c)$. We applied a clustering method one hundred times with different initial cluster centers and used the average as the clustering performance. We used k-means, k-medoids, DBA [5], and k-shape [6] as baselines. Since k-medoids-based methods can use any distance metric, we applied multiple distance metrics: Manhattan distances (L1), Euclidean distances (L2), EMD, and dynamic time warping (DTW). We set 10 as the number of clusters and 5 as the number of centers in mini-batch top- n k-medoids ($n = 10, k = 5$).

Table 1 shows the evaluation results. We do not list the performance of k-shapes because the performance of k-shapes was over 10 times worse than other clustering methods. We evaluated the performance of mini-batch top- n k-medoids by comparing #2 and #6, #3 and #7, #4 and #8, and #5 and #9. Except for cases with DTW, mini-batch top- n k-medoids performed better than k-medoids. Based on the comparison, the mini-batch top- n k-medoids outperformed the other clustering methods in this evaluation.

Distance metrics defined in Euclidean space were better than EMD and DTW distance metrics designed for time-series data. EMD and DTW handle shift-invariances, one of the biggest issues in time-series data processing. We handle shift-invariances by using a sliding window, not a distance metric. Therefore, EMD and DTW would not interact well with this evaluation.

Table 1. Clustering performance when the number of clusters was 10 (k=10). In this case the clustering performance is the average EMD between cluster centers and four base waves.

ID	Method	Loss	ID	Method	Loss
#1	k-means	8.949	#6	Mini-batch top-n k-medoids + L1	5.185
#2	k-medoids + L1	6.519	#7	Mini-batch top-n k-medoids + L2	5.821
#3	k-medoids + L2	6.000	#8	Mini-batch top-n k-medoids + EMD	7.292
#4	k-medoids + EMD	7.850	#9	Mini-batch top-n k-medoids + DTW	15.061
#5	k-medoids + DTW	14.535	#10	DBA [5]	9.277

Experiment with the real CGM dataset: We applied our interpretation method to a CGM dataset (created through clinical trials) containing 223 waves from 163 real patients over a 2-week period. We targeted patients diagnosed with type 2 diabetes mellitus living in Japan. The target device was Abbott Freestyle Libre³.

We created two labels based on the patients’ blood glucose (BG) statistics. The first label was created from the average of BG and separated the waves into three groups: the average BG is (1) less than 110, (2) more than 110 but less than 140, and (3) more than 140. The numbers of the waves were 129, 80, and 13. The second label was created from the standard deviation of BG and separates the waves into three groups: the standard deviation of BG is (1) less than 30, (2) more than 30 but less than 50, and (3) more than 50. The numbers of waves were 142, 51, and 29. In the experiments, we applied this method by changing the number of clusters, as shown in Tables 2. We set 5 as the number of the centers in mini-batch top-n k-medoids (n = 5) and uses L1 as a distance metric. We used p-value to measure correlation between a label and a pattern. We investigated patterns that occurred more than 100 times and assumed that a pattern whose p-value was less than 0.1 was label-specific.

In the first label, the average of BG, we obtained 686 patterns, and the p-values of 58 patterns were less than 0.1 when there were 30 clusters. When there were 20 clusters, the number of patterns was the largest. In the second label, the standard deviation of BG, we obtained 691 patterns, and the p-values of 58 patterns were less than 0.1 when the number of clusters was 40.

Figure 2 is two examples of label-specific sequential patterns in each label. In both examples, the waves were not observed in group 3, and they highly correlated with groups 1 and 2. When replacing a cluster ID with a cluster representative wave, we selected one that had minimum loss ϕ_x in the cluster. Our aim is to propose an interpretation method rather than give medical insight, so we do not discuss the patterns.

4. Conclusion

In this paper, we focused on a better interpretation of CGM values. We propose an interpretation method of extracting characteristic sequential patterns using mini-batch top-n k-medoids that provides accurate cluster centers. By clustering the data, we group similar elements of data to find patterns more effectively.

Table 2. Results of the first label created from the BG average (AVG) and the second label created from the standard deviation of BG (STD)

Num. of clusters	20	25	30	35	40	45	50
Num. of patterns (AVG)	768	687	686	680	689	644	659
Num. of label-specific patterns (AVG)	54	50	58	43	48	46	48
Num. of patterns (STD)	791	694	688	691	691	666	676
Num. of label-specific patterns (STD)	53	45	44	43	58	47	56

**Figure 2.** Examples of label-specific sequential patterns produced from the CGM dataset. The waves on the right side were created from the label based on the BG average. The waves on the left side were created from the label based on the standard deviation of BG.

We conducted two evaluations. In the first experiment on manually created dataset, we show that mini-batch top-n k-medoids outperformed the baselines. In the second experiment, we applied our interpretation method to a CGM dataset containing 223 waves created from 163 real patients over a 2-week period. We created two labels based on blood glucose statistics, and extracted label-specific sequential patterns.

Introducing New Measures of Inter- and Intra-Rater Agreement to Assess the Reliability of Medical Ground Truth

Andrea CAMPAGNER ^{a,b} and Federico CABITZA ^{b,1}

^a*IRCCS Istituto Ortopedico Galeazzi, Milano, Italy*

^b*University of Milano-Bicocca, Milano, Italy*

Abstract. In this paper, we present and discuss two new measures of inter- and intra-rater agreement to assess the reliability of the raters, and hence of their labeling, in multi-rater settings, which are common in the production of ground truth for machine learning models. Our proposal is more conservative of other existing agreement measures, as it considers a more articulated notion of agreement by chance, based on an empirical estimation of the precision (or reliability) of the single raters involved. We discuss the measures in light of a realistic annotation tasks that involved 13 expert radiologists in labeling the MRNet dataset.

Keywords. inter-rater agreement, reliability, Ground Truth, Machine Learning

1. Introduction

Data science research needs valid and reliable data to enable the comprehension of the represented phenomena, and sound statistical inference and prediction about those phenomena, that is the definition of predictive models, e.g., by machine learning methods that can help human decision makers classify and interpret the reality of interest.

In many domains, like medicine, phenomena are increasingly measured by sensors, but are still to a large extent described by human observers, who are supposed to produce data in the endeavor to provide accurate and complete representations, by which to detect effects, trends and differences and build reliable prediction models out of them, what is then called *Ground Truth*.

In the light of the unavoidable fallibility of human observers in providing an ever true representation, in domains characterized by high uncertainty, ambiguity and variability of relevant conditions, like medicine, ground truth datasets are built by combining multiple observations and ratings (i.e., labels), and averaging between them, to associate “the one best” label to each case or object of interest. This is the process by which data scientists can bring together subjective ratings (that is how a single rater sees and interprets a given phenomenon) and create a reliable inter-subjective labelling, which is intended to be the most objective representation of the reality of interest [1].

¹Corresponding Author: Federico Cabitza, federico.cabitza@unimib.it

Assessing observer variability, that is the extent multiple raters agree (or disagree) in providing a unique interpretation (that is label, or evaluation), is then important to assess the reliability of the ground truth by which to build predictive models from empirical observations. In the literature there are many measures (e.g., Fleiss' Kappa, Cohen's Kappa, Krippendorff's α) and any of them present pros and cons [2]. In particular, to assess inter-rater agreement, the Krippendorff's α is particularly indicated (although seldom used in medicine and by ML scholars) as it is robust with respect to chance effects and missing values.

However, this measure, as the other ones, adopts a naive model of chance, by which to assess the degree by which multiple observers agree with each others beyond the extent they do so by chance. In particular, no measure considers the expertise of the raters involved, nor their confidence in their specific ratings: in short the reliability of their ratings. This brings us to consider an aspect that is seldom considered: how to assess the reliability of the raters involved, beyond self-assessment? This can be evaluated in many ways: we investigated the relationship between this construct and the extent raters agree with themselves in judging the same phenomenon multiple times over time, and hence they do not take guesses. We call this degree, *self-agreement*, while others refer to it with the expression *intra-rater agreement* (e.g., [3]).

In this paper, we will present two new metrics to assess both self-agreement and inter-rater agreement in order to contribute to the existing literature and provide a better tool to assess the reliability of multi-rater labeled datasets.

2. Method

In this Section we first provide a decision-theory based derivation of a measure for *self-agreement*, intended as the probability that a decision-maker gives the same interpretation of the same phenomenon consistently. Next, we use the self-agreement indicator to define a novel chance-adjusted measure of *inter-rater reliability* that we denote as p . Let $C = \{0, 1, \dots, n-1\}$ be the set of possible class labels, $p = \langle p(0), \dots, p(n-1) \rangle$ be the proportion of 0s, 1s, ..., $n-1$ s in the actual labelings by multiple raters (we assume that these reflect the real class proportions in the reality of interest).

We assume a two-step decision procedure: first the decision maker flips a biased $n+1$ faced coin to choose between *random choice* (x) and *peaked choice* (y_0, \dots, y_{n-1}). Then:

- If the decision maker chose random choice, then she selects one class according to distribution p ;
- Otherwise, if she chose peaked choice, she reports one value (which depends on the specific peaked distribution chosen) with probability 1. Notice that while each peaked distribution assigns probability 1 to a single alternative, the specific peaked distribution is chosen according to (y_0, \dots, y_{n-1}) , which allows to encode possible degree of uncertainty of the rater when she does not guess completely at random.

This decision-making model conforms to standard decision-theory where a decision maker is usually modeled as a probabilistic device in particular, our model represents a generalization of the decision model proposed by Krippendorff as a justification for his α metrics [4], in which raters possess different and unrelated probabilities of selecting among the alternatives at random (e.g. due to their different expertise levels).

How can we find x and y_0, \dots, y_{n-1} given m o_1, \dots, o_m observations of the decision-maker repeating the same annotation task (i.e. annotating multiple times the same case)? Let $d(0), \dots, d(n-1)$ be the observed proportion of 0, 1, ..., $n-1$ labels, respectively, among o_1, \dots, o_m (notice that this is a maximum likelihood estimation of the parameters of a nominal distribution). We can find x, y_0, \dots, y_{n-1} selecting the solution to the following system by maximizing the entropy:

$$\begin{cases} \forall i. d(i) = x * p(i) + y_i \\ x + \sum_i y_i = 1 \\ \forall i. x, y_i \geq 0 \end{cases} \quad (1)$$

We define the *self-agreement* of the observer on label class i as $SA_i = [x * p(i) + y_i]^2 = d(i)^2$ and their overall self-agreement as $SA = \sum_i SA_i$. Notice that SA_i is the probability that the observer gives the same label i when it is asked to give a label to the same object twice and thus it coincides with the *Gini impurity*.

Starting from our definition of self-agreement, we want to define a measure of inter-rater reliability, i.e. a measure of the extent a set of raters agree in labeling a set of cases or objects. Specifically, we want to define a measure ρ that takes into account the fact that, because that raters do not have perfect self-agreements, mutual agreements may arise due to chance; thus, we want ρ to properly discount this case.

Given two raters i, j and a case x we can find the probability

$$P((i, j) \text{ genuinely agree on } x | (i, j) \text{ agree on } x) \quad (2)$$

by a direct application of *Bayes' rule*. Denoting as $y_k^i(x)$ the value of y_k for rater i on case x , we note that this represents the probability that rater i *genuinely* asserts label i on case x . Denoting as $c_i(x)$ the labeling provided by rater i on case x and supposing that $c_i(x) = c_j(x)$, we can see that, assuming that the raters i, j annotate case x independently:

$$P((i, j) \text{ genuinely agree on } x) = y_{c_i(x)}^i(x) * y_{c_j(x)}^j(x) \quad (3)$$

and

$$P((i, j) \text{ agree on } x) = P((i, j) \text{ genuinely agree on } x) + P((i, j) \text{ agree by chance on } x) = y_{c_i(x)}^i * y_{c_j(x)}^j + p[c_i(x)] * x^i * y_{c_j(x)}^j + p[c_j(x)] * y_{c_i(x)}^i * x^j + p[c_i(x)] * p[c_j(x)] * x^i * x^j \quad (4)$$

Then, denoting the ratio of the probabilities in Equations 3, 4 as *Genuine Agreement Effect* (GAE), we can express the ρ measure as:

$$\rho = \frac{1}{|U|} \sum_x \frac{1}{\binom{|D|}{2}} \sum_{i \neq j \in D} \delta(c_i(x), c_j(x)) * GAE(i, j) \quad (5)$$

where $\delta(x, y) = \begin{cases} 1 & x = y \\ 0 & \text{otherwise} \end{cases}$, U is the set of cases and D the set of raters. Notice

that when the sample size to estimate the values of the y_k^i factors is small, the estimate

obtained via the exact methods is not robust when computing the value of ρ , especially if the value were computed on only a small set of cases and then propagated to the remaining ones (e.g. by averaging). In these cases a more robust but approximate estimate can be obtained by considering ignoring the specific probability of getting a particular peaked choice distribution and only considering $\sum_k y_k^i$ as a measure of the ability of rater i of providing self-consistent annotations.

3. Results

In order to test our proposed measures we considered a dataset obtained by a realistic experiment of knee *Magnetic Resonance Imaging* (MRI) annotation. Specifically, we asked 13 radiologists from the IRCCS Orthopedic Institute Galeazzi of Milan (Italy) to annotate 417 MRIs from the well-known MRNet dataset²: in particular, the doctors were asked to assess, for each of these images, the presence of abnormalities (thus, the considered problem was a binary classification setting, i.e. $C = \{0, 1\}$). Furthermore, the doctors were also asked to assess the complexity of each case and the confidence in their annotations, on a 4- and 5-value scale, respectively.

In order to apply our measure, we first had to estimate the self-agreement of each of the raters. In order to do so, we first chose two cases randomly among the ones considered of medium to high difficulty (between 2 and 3 in a 1 to 4 scale) by one of the most experienced radiologist in the panel of experts involved. Then, we inserted these two cases multiple times in the dataset of cases to be labelled, replicating them for 6 times each: in so doing, the dataset had 10 more cases. These replicated images were placed randomly in an annotation sequence (encompassing more than 200 cases) to make more difficult for the radiologists to understand that they had already examined and assessed those cases. Considering the spread, in terms of interquartile range (IQR), in the complexity rating and the varying confidence in the interpretation of these identical cases, we can conjecture that the replicated cases were likely considered different cases by all of the radiologists (First case: complexity IQR = 0.63, confidence IQR = 0.5; Second group: complexity IQR = 0.5, confidence IQR = 0.4).

In regard to the first case, we obtained an average self-agreement of 0.58 ± 0.03 (95% confidence interval, $\min = 0.5$, $\max = 0.72$) For the second group of images, we obtained an average self-agreement of 0.51 ± 0.01 ($\min = 0.50$, $\max = 0.56$): notice that these values are close to the minimal value for SA which, for the binary case, is 0.50. Averaging between the two groups the average self-agreement was 0.54 ± 0.02 ($\min = 0.5$, $\max = 0.64$).

In the computation of the ρ , for each agent i , we considered the values $y_0^i + y_1^i$ estimated on the whole group of 12 repeated images. We obtained a value of $\rho = 0.46$, while for the same dataset we obtained a value of Fleiss' $k = 0.63$ and Krippendorff's $\alpha = 0.63$.

4. Discussion

The above results show how our measure is much more conservative than the others proposed to assess inter-rater agreement. The small difference between the latter measures

²<https://stanfordmlgroup.github.io/competitions/mrnet/>

can be explained by the fact that there was a near perfect class balance: indeed both k and α consider the class balance in order to model chance effects. Furthermore, the large difference between the ρ and the values of the other metrics can be explained observing that the observed self-agreement were indeed very low and the same holds for the obtained y_k^i value (in most cases the value of x^i was near to 0.5). In fact, to obtain a value of $\rho \sim 0.63$ on the dataset, an average GAE around 0.75 would be needed. This shows that, differently from α (and k), the ρ takes into account a model of the rating reliability of the raters involved, and hence it yields a more realistic measure of their agreement: for example, if all raters exhibited a perfect self-agreement (thus $GAE = 1$) we would obtain a value $\rho = 0.82$ while the values for α and k would not change.

Moreover, one could wonder what threshold should be set to assess whether the agreement is sufficient to consider the data reliable, that is what the so-called *smallest acceptable reliability* is [4]. Unfortunately, any proposal of such a threshold would be laden with some extent of arbitrariness. Krippendorff suggests to “not accept data with reliabilities whose confidence interval reaches below the smallest acceptable reliability [...], for example, of .800, but no less than .667” [4](p. 242). An α or an ρ below 0.667 would mean that only two thirds of the data are labelled to a degree better than chance”. This recommendation challenges a much more popular way to interpret agreement scores since the 1970s by [5], that is much more indulgent (a score of .21 is considered an indicator of *fair* agreement; .41 *moderate*; .61 *substantial*).

As said above, differently from α , the ρ takes into account a model of the rating reliability, and hence it yields a more realistic measure of their agreement. In this first formulation, we have considered self-agreement as a proxy of the rater reliability. Since measuring self-agreement with surreptitious repetitions can be intricate, Formula 5 can alternatively be integrated with a measure of the raters’ confidence in the interpretations given (the higher the confidence on a rating, the higher the reliability of that rating as the rater is stating they are not taking a guess). Although this sounds reasonable, yet we did not find confidence to be highly correlated with self-agreement (*correlation* = 0.22, *p* – value = 0.46).

In this regard, however, we should emphasize that low ρ or *SA* scores should not be used as proxy of rating skills, or to judge how good the raters are: in the MRNet study, the 13 radiologists achieved a remarkable average performance of .82 (min: .78, max: .86) in re-annotating the original, low-res dataset on standard monitors and with no incentives. Rather, what low ρ or *SA* scores in ground truthing by experts indicate is the intrinsic ambiguity and complexity of medical phenomena; the over-ambition to pinpoint them with clear-cut labels; and the reckless risk to delegate judgment or advice to classifying machines that interpolate those labels as a way to resolve uncertainty.

Abstract. Eye tracking studies have demonstrated deficits in attention in individuals with Autism Spectrum Disorder (ASD) for a range of different social attention-based tasks. Here we examined social attention skills in a large sample of ASD participants (n = 120), using eye tracking data from a social information processing task, and compared them with a typically developing (TD) group (n = 35). Assuming eye movement parameters are random variables generated by an underlying stochastic process, we modeled the fixation sequences of participants in ASD and TD groups with a Hidden Markov Model. The Regions of Interests (ROIs), modeled as hidden states, corresponded to the true ROIs with a prediction accuracy of >90% for each group. The transition between ROIs revealed bias towards a specific area in the scene in ASD group, which deviated from the TD group. Objective time-dynamic measures of gaze patterns can potentially serve as useful endpoints in ASD diagnosis. **Clinical Trial Registration:** NCT02299700.

Keywords. Autism Spectrum Disorder; eye tracking; Hidden Markov Model.

1. Introduction

Tracking of eye movements allows collection of high-density spatiotemporal data that can provide a rich source of information related to underlying cognitive processes. Several studies have proposed different computational methods to infer observers' characteristics during tasks such as counting, searching, memorizing, or viewing static artificial or natural scenes, that are informative of cognitive processes. These methods broadly range from extracting eye tracking parameters like fixation duration, number, dispersion etc. directly from the data [1]; incorporating spatial information by creating heatmaps, which are 3-D objects (x-coordinate, y-coordinate, fixation density) representing spatial distribution of eye position at a given time [2]; converting eye movement trajectory to a chronological sequence of fixations within pre-defined regions of interest followed by using geometric-based distances metrics to compare scan paths [3]; or using probabilistic approaches to model eye movement [4].

Eye tracking data has been studied as an indicator of social attention in Autism Spectrum Disorder (ASD). Attention to social information is impaired in individuals with ASD, including limited attention to eyes and faces, increased attention to non-social stimuli, increased attention to detail and difficulty with shifting attention compared to typically developing (TD) controls [5]. Commonly, Regions of Interests (ROI) are identified on static images or sequentially on dynamic videos and time spent viewing a prespecified ROI is used to study gaze differences between ASD and TD

¹ Corresponding Author, Meenakshi Chatterjee, Digital Phenotyping, Janssen Research & Development, LLC, Spring House, PA 19477 USA; E-mail: mchatte4@its.jnj.com

groups. Although simple and intuitive, this approach does not capture the dynamic nature of gaze and involves a labor-intensive process of manual labeling of ROIs.

Using data obtained from an observational study collected from the Janssen Autism Knowledge Engine® (JAKE®) [6,7], here we present findings on measurement of eye tracking data from a *Social Information Processing task*. We propose a Hidden Markov Model (HMM) based approach, a time-series probabilistic model, to analyze complex gaze trajectories in ASD and TD groups. Since eye fixation during a task is conditioned on previous fixations, eye movements can be represented as a Markov process. HMM is a natural fit for this problem - it models the specific ROIs participants look at as *hidden states* (eliminating the need to manually label ROIs) and captures the transition among those ROIs (incorporating the temporal dynamics of eye movement).

2. Study design

2.1 Participants: This study was a part of large prospective, 10-week long observational clinical trial conducted at 9 study sites in the US and enrolled 144 ASD and 41 TD participants in total aged between 6 and 64 years [7]. At the study sites, participants completed multiple passive viewing tasks presented on a 23-in. computer screen (1920-by-1024 pixels). Table 1 shows the characteristics of participants for which valid data was available when performing the social information processing task.

Table 1. Characteristics of ASD and TD participants.

	Age (years): Mean (SD)	Age (years): Median (Range)	Male: n (%)
ASD (n = 120)	14.63 (8.25)	12 (6 - 54)	92 (76.67)
TD (n = 35)	16.06 (12.6)	12 (6 - 63)	24 (68.57)

2.2 Social information processing task: Here we focus specifically on the results from a viewing task called the social information processing task. Participants viewed a video of a female actor engaged in child-directed speech against a background of objects, such as toys and an iPad. Detailed description of the video can be found in [8]. The length of the video was 73 seconds with 4 predefined conditions presented over multiple episodes, designed to reflect important aspects of social interaction requiring different demand characteristics: a) Activity: where the actor is making a snack. No direct actor’s gaze or speech cues is present; b) Dyadic Bid: where the actor faces and speaks directly to the camera; c) Joint Attention: where a walking toy robot suddenly begins to move towards the actor, which distracts her from her activity and makes her turn toward that toy; d) Moving Toy: where the toy robot is moving, but the actor looks away at a different toy placed on a wooden stand, located diametrically opposite to the moving toy robot. Figure 1 shows snapshots from the 4 conditions.

Figure 1. Representative snapshots from 4 predefined conditions in social information processing task.

Participants freely viewed the video while sitting in a comfortable chair ~60 cm from the screen. Tobii X2 eye tracker, mounted below the screen, collected participants’ eye movement data at a sampling rate of 30 Hz. iMotions Biometric Research Platform was

used for stimulus presentation, synchronization and automatic calibration. Before start of the task, a cartoon was placed on a center of the screen to cue participant's attention.

3. Analyses

3.1 HMM for eye movement analysis: A Markov process is a memory-less stochastic process where the probability distribution of the next event or state (in a sequence of events) depends only on the current state and not on the sequence of states preceding it. An HMM is based on augmentation of a Markov process where the system to be modeled has unobservable or *hidden* states. HMMs are suitable for modeling sequential data varying over time and is specified by the following components:

$S = s_1 s_2 \dots s_K$	a set of K states
$A = a_{11} \dots a_{ij} \dots a_{KK}$	a transition probability matrix A , a_{ij} being the probability of moving from state \hat{i} to state \hat{j} , s.t. $\sum_{j=1}^K a_{ij} = 1 \forall i$
$O = o_1 o_2 \dots o_T$	a sequence of T observations
$B = b_i(o_t)$	emission probabilities, each representing the probability of an observation o_t being generated from a state \hat{i}
$\pi = \pi_1 \pi_2 \dots \pi_K$	Prior/initial probability distribution of states, s.t. $\sum_{i=1}^K \pi_i = 1$

Figure 2. ROIs manually drawn on areas of scene.

In the context of eye movement modeling, the fixation sequence of a participant constitutes a sequence of observation for the HMM. The hidden states of HMM represent Regions of Interest (ROIs) when the participant is viewing the video. The possible ROIs that participants could be viewing during the video is shown in Figure 2. Here we assumed that the distribution of eye fixations on each ROI follows a Gaussian distribution, so the emission densities corresponding to the fixations distribution in each ROI was modeled as two-dimensional Gaussian distribution:

$$B = N_i(m_i, \Sigma_i)_{i \in [s_1, \dots, s_K]} \quad m_i \text{ is the center, } \Sigma_i \text{ is the covariance of } i^{th} \text{ state emission.}$$

We modeled the three ROIs: *hair*, *eye* and *mouth* as a single hidden state and called it *face*. The transition from one ROI (hidden state) to another represents a saccade, and the probabilities of these transitions are summarized in the transition matrix. The prior specifies the probability distribution of the first fixation. The fixation sequences of all participants in each group (ASD and TD) were modeled using a single HMM. To avoid convergence to local minimum, the ASD (and TD) model was trained 100 times with different initial parameters for Gaussian distributions of ROIs, and the model with the highest log-likelihood of the data was selected. The resultant model parameters obtained were the transition matrix, emission densities and priors. From the transition matrix, we quantified the randomness associated with transitioning among different ROIs, by computing the entropy of trajectories of a Markov process as derived in [9].

3.2 Validation of predicted hidden states with Regions of Interest (ROI): To assess if the hidden states or the ROIs predicted by the model for each group correspond to the true ROIs (Figure 2), normalized confusion matrices were generated. Confusion matrix visualizes the performance of HMM model where the rows and columns represent the instances in true and predicted ROIs respectively.

4. Results

Figure 3 shows the accuracy of predicted ROIs when validated with true ROIs for the ASD group (Figure 3A) and the TD group (Figure 3B). Overall prediction accuracy for all ROIs taken together were 92.73% and 94.55% for ASD and TD groups respectively.

Figure 3. (A) True ROIs (left), predicted ROIs (middle), normalized confusion matrix (right) for ASD group. (B) True ROIs (left), predicted ROIs (middle), normalized confusion matrix (right) for TD group.

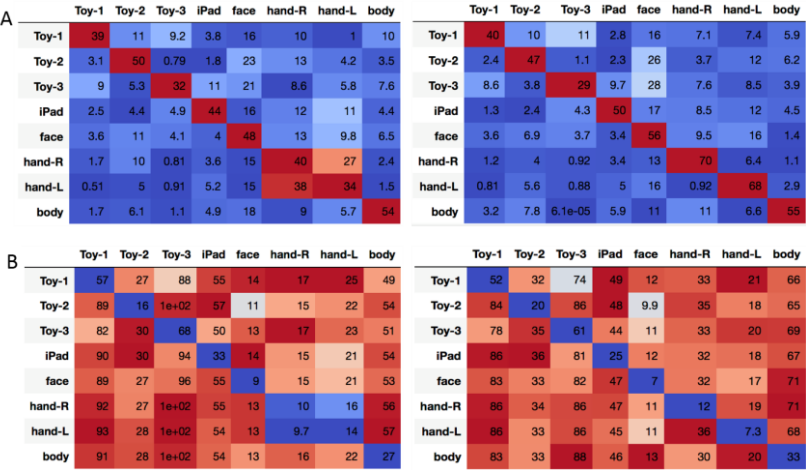

Figure 4. (A) Transition matrices for ASD (left) and TD (right) group; each cell contains probability values multiplied by 100; (B) Markov entropy matrices for ASD (left) and TD (right) group.

All 3 toys in the video array, *iPad*, *face* and *hands* were predicted with high accuracy (>85%) in each group, however accuracy for prediction of *body* fell to 75.5% and 70.9% for ASD and TD groups respectively. The model automatically splits the *hands* into 2 regions of interest: the left hand, *hand-L* and the right hand, *hand-R* (for the purpose of an easy visualization, *hand-L* and *hand-R* are combined and represented as *hands* only in Figure 3). The probability distribution of first fixation indicated that *body* is the most probable initial fixation both for the ASD group (prior probability = 0.95) and TD group (prior probability = 1), with *iPad* being the next most likely initial fixation for ASD group. The fact that both groups initially fixate on *body* could possibly be a manifestation of the experimental design, wherein participants' gaze could still be directed at the cartoon on center of the screen (shown at the beginning of

the task) which falls within the *body* ROI, even slightly after task has started. Figure 4A shows the transition matrix for each group. The TD group exhibited a higher probability to continue fixating at the *face* when they are already fixated at the *face*. ASD group also deviated from the TD group in the way they scanned the *hands*- when participants in the ASD group fixate at the right hand, they are likely to next shift their gaze to the left hand. Similarly, when ASD participants fixate at the left hand, they are likely to next shift their gaze to the right hand. Thus, ASD group was more likely to switch between the two hands than TD group. This stereotypic nature of scanning the *hands* was also captured by the entropies of the transition matrices (Figure 4B), where the entropies of switching between two *hands* (as well as entropies of switching to *hands* from any other ROI) were much lower in ASD group than that in TD group.

5. Conclusion & Future Work

Here we presented a simple methodological framework based on Markov chain and information theory to cut complex eye tracking trajectories into interpretable elementary measures with the least amount of data manipulation or introduction of free parameters as possible. This approach identified the ROI observers look at without requiring manual pre-specification and captured the dynamic nature of gaze patterns by modeling the transition probabilities of the ROIs. One HMM was built for each group, hence could not capture the variability in viewing patterns across participants which can be relevant particularly in ASD group. The ASD group also spent significant time viewing the stimulus background which could bias the choice of hidden states of the model. Finally, the primary focus of the main study was to maximize collection of data in the ASD group, which led to a smaller and unbalanced TD group. Future work will augment the model by introducing a prior to HMM that will model spatial distribution of the moving ROIs, incorporating time spent viewing non-stimulus, building an HMM for each participant and correlating the participant level measures with clinical scales.

Medical University of Graz, Austria

Abstract. Acronyms frequently occur in clinical text, which makes their identification, disambiguation and resolution an important task in clinical natural language processing. This paper contributes to acronym resolution in Spanish through the creation of a set of sense inventories organized by clinical specialty containing acronyms, their expansions, and corpus-driven features. The new acronym resource is composed of 51 clinical specialties with 3,603 acronyms in total, from which we identified 228 language independent acronyms and 391 language dependent expansions. We further analyzed the sense inventory across specialties and present novel insights of acronym usage in biomedical Spanish texts.

Keywords. Acronym resolution, Clinical specialties, Natural Language Processing, PubMed, Sense inventory, Spanish

1. Introduction

An important normalization task in clinical Natural Language Processing (NLP) is the identification and resolution of short forms, e.g. “Human Immunodeficiency Virus (HIV)”. Existing approaches can be distinguished between those that focus on documents where the expansion is explicitly contained (e.g. in scientific articles) and those where the resolution of the acronym is left to the reader (e.g. in clinical narratives). While the former case is mostly addressed by rules, heuristics, and statistical analyses, the latter is usually addressed by using external dictionaries. In both cases, ambiguity arises when an identified acronym may have different expansions (e.g. RA for *Right Atrium* or *Rheumatoid Arthritis*). The problem of ambiguity has been addressed by analyzing the contexts in which the acronym may exist; however, acronym dictionaries in which expansions are linked with possible contexts rarely exist [1].

Several studies have proposed sense inventories that are automatically obtained from MEDLINE or other openly accessible corpora by exploring acronym-definition

¹Corresponding Author: Pontificia Universidad Javeriana, Cra. 7 No 40-62, Bogotá, Colombia; E-mail: pomares@javeriana.edu.co

pairs commonly found in scientific texts. Some of the strategies considered for English abstracts include manually-created pattern matching rules [2,3]; statistics-based word collocations[4,5]; or a mix of both [6]. A seminal study on this topic has been pre-sented by Schwartz and Hearst [7] who proposed a simple algorithm in which possible candidates identified using length heuristics are used to map parenthesized short form-definition-pairs with an alignment-based strategy.

Languages other than English came into focus for short form expansion more recently. In Spanish, the 2018 BARR2 Task [8] explored clinical acronym disambiguation, with a focus on acronym identification on the first subtrack. The winning team of Sánchez-León [9] proposed the application of regular expressions on content of biomedical websites, while Montalvo et al. [10] applied the Schwartz & Hearst algorithm on SNOMED CT to biomedical websites.

This paper contributes to acronym resolution in Spanish clinical texts through the semi-automatic creation of acronym repositories from non-clinical texts using a resource that guides disambiguation. This resource is composed of a set of acronym inventories classified by clinical specialty and characterized by specialty-specific acronym expansions. Our main goal is to demonstrate that the generation of a sense inventory classified by specialty helps acronym resolution by reducing sense ambiguity. To the best of our knowledge, we are the first to apply the Schwartz & Hearst algorithm to the full Spanish subset of MEDLINE and provide our results stratified by clinical specialty.

2. Method

Figure 1 depicts the construction of the sense inventory classified by clinical specialty.

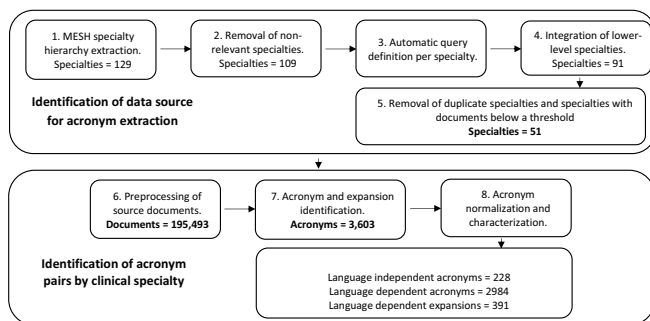

Figure 1. Overview of acronym identification and classification

Identification of data source for acronym extraction: We firstly identified specific branches of the MeSH thesaurus² related to each clinical specialty (step 1). We considered MeSH terms denoting clinical specialties (step 2) and other terms extracted from the “See Also” section of the MeSH hierarchy (step 3) and, from them, only the specialties in the first two levels of the MeSH hierarchy (step 4). Finally, we excluded duplicated

²<https://meshb.nlm.nih.gov>

specialties (e.g. gynecology as “Specialties, Surgical” and as “Reproductive Medicine”) and specialties with less than 250 Spanish titles in their MEDLINE record (step 5).

We explored the MeSH thesaurus and automatically queried documents in PubMed using Biopython³ for matches on either (a) affiliation, (b) title, or (c) MeSH tags.

Identification of acronym pairs by clinical specialty: Once we obtained the relevant documents, we pre-processed their titles and abstracts (step 6) and applied the Schwartz & Hearst algorithm (step 7).

We normalized all acronym expansions to lower case and characterized each acronym/expansion pair by the following features (step 8): (i) intra-frequency, the frequency of the acronym within a clinical specialty; (ii) inter-frequency, the frequency of the acronym across all specialties. (iii) uniqueness across specialties, the number of specialties where the acronym was found; (iv) intra-specialty and (v) inter-specialty ambiguity, the number of different senses found for the same acronym within a specialty or across all specialties, respectively.

We finally (step 9) analyzed the level of language-independence of acronyms and their expansions because we observed acronyms that derived from a different language (mostly English and Latin) together with Spanish expansions. In these articles where acronyms and expansions were identified in both languages, we performed a language independence analysis and classified acronyms automatically into three groups: (i) language-independent acronyms, acronyms and their corresponding expansion are used indistinctly in any language, e.g., “NEWSQOL” (“Newcastle Stroke-specific Quality Of Life measure”); (ii) language-dependent acronym, acronyms whose value and expansion are different for each language, e.g., “MS” (“Multiple Sclerosis”, English) and its corresponding “EM” (“Esclerosis Múltiple”, Spanish); and (iii) language-dependent expansion of acronyms used indistinctly in any language with expansions translated into the document language (the translation does not necessarily coincide with the acronym creation rules), e.g., “ANCA” (“Anti-Neutrophil Cytoplasmic Antibodies”) and “ANCA” (“anticitoplasma de neutrófilos”).

3. Results

The resource⁴ generated is composed of 51 dictionaries with 3,603 acronyms identified from the Spanish subset of MEDLINE. Figure 2 illustrates the number of acronyms vs. the number of titles analyzed per specialty. The analysis of this relationship showed that out of the group of specialties with more than 1,000 titles available, pediatrics, rehabilitation, radiology, psychiatry, and orthopedics are the specialties with the higher ratio of acronyms per title. For instance, pediatrics has approximately one acronym in every 22 titles / abstracts.

We analyzed the ambiguity of acronyms by comparing the number of possible expansions in the corpus and their reduction when they were analyzed by specialty (Figure 3). The x axis shows the number of possible expansions in a specialty-independent inventory, while the y axis shows the average number of expansions in the specialties in which the acronym was used. The dot size represents the number of acronyms with the

³<https://biopython.org/>

⁴Available at <https://github.com/plubeda/spanish-acronyms-pubmed>.

Figure 2. Acronyms per specialty and number of source document titles.

same behavior. We found that the acronyms DE (12), EC (12), CC (11), II (10) are the most ambiguous acronyms as they have ten or more possible expansions. We reduced the overall ambiguity from 1.32 to 1.06 senses/acronym, a reduction of 81% ambiguity (excess over 1) on average. Considering only ambiguous acronyms, we reduced it from 2.71 to 1.28 senses/acronym, a mean reduction of 84%.

Figure 3. Number of expansions before and after specialty classification.

Finally, Figure 4 depicts the similarity of the specialties with respect to the acronyms they use. The height at which any two specialties merge indicates the joining order: a smaller height represents a stronger relationship; e.g., “obstetrics” and “perinatology” are the most similar because they share 92% of their acronyms.

4. Discussion and Conclusion

The generated resource supported the hypothesis that creating a sense-inventory of acronyms classified by specialty reduces the level of ambiguity when compared to a specialty-independent sense inventory. Therefore, it can be used to improve contextual knowledge about an acronym and thus better disambiguate its meaning during the resolution process. The development of this resource also made it possible to identify the specialties in which more acronyms are used and those specialties with stronger links in terms of the acronyms used.

The proposed method can be expanded to any other language that has available resources in PubMed. In the future, we plan to use the generated resource for pre-processing electronic health records. We also would like to extract contextualized word embeddings for each acronym and make them available as features together with the dictionary resource.

Abstract. Iris is a system for coding multiple causes of death in ICD-10 and for the selection of the underlying cause of death, based on a knowledge base composed by a large number of rules. With the adoption of ICD-11, those rules need translation to ICD-11. A pre-project has been carried out to evaluate feasibility of transition to ICD-11, which included the analysis of the logical meta-rules needed for rule translation and development of a prototype support system for the expert that will translate the coding rules.

Keywords. Classifications, ICD-10, ICD-11, ontology mapping

1. Introduction

With its adoption by the 72th World Health Assembly in May 2019, ICD-11 (International Classification of Diseases, Revision 11) will become the new standard for coding diseases and health problems. For mortality statistics, the ICD coding is performed with the use of semi-automated coding systems, mainly Iris [1].

Iris is a system for coding multiple causes of death in ICD-10 and for the selection of the underlying cause of death. Iris is based on the international death certificate form and coding rules provided by WHO (World Health Organisation). The core component of Iris are the decision tables, currently based on ICD-10 codes. For the transition of Iris to ICD-11, it will be necessary to translate the decision tables and to allow them to include all the features of the new revision.

This transition is expected to have a big impact on the system transition and use. Periodic revision of the ICD is essential to stay abreast of advances in medical science and changes in medical terminology [2,3]. Institutionally, revision of the ICD requires an enormous investment of national resources to revise software, training, publications, edit procedures, etc [4]. For the Iris transition to ICD-11, classification and coding experts are needed. To support their work, formal procedures are needed to ensure the correctness of the transition and validation of the system.

A pre-project has been carried out to evaluate feasibility of transition to ICD-11, which included the analysis of the logical meta-rules needed for rule translation and development of a prototype translation support system aimed at the expert [5]. This paper describes the logical rules identified for translating from ICD-10 to ICD-11 with their consequences from the point of view of automation and human expert intervention, with an overview of the prototype, and evaluation of efforts needed.

1.1. Decision tables

The decision tables form a knowledge base of relations between pairs of codes (representing the causes of death reported on the death certificate) that must be taken into consideration during the application of the steps for the selection of the underlying cause.

This knowledge base was first developed by the NCHS (US National Center for Health Statistics) for the ACME system [6]. Successively it has been embedded in the new automated coding system Iris and updated on the basis of the recommendations of the Mortality Reference Group, which operates in the network of the WHO Collaborating centers for the Family of International Classifications (WHO-FIC) [7].

In practical terms, the decision tables are a list of possible kind of relations between pairs of terminal code. The relation between the codes are specified as “rule type”, which are used in the different steps of selection.

1.2. Mapping between classification versions

Along with ICD-11, the WHO releases the mapping table between the ICD-10 and ICD-11 classification. The mapping table contains the mapping of both terminal codes and higher categories which can be used to add detail.

The mapping between the ICD-10 and ICD-11 entities can be specified by cardinality as: 1×1 (equivalent), $1 \times n$, $n \times 1$ and $n \times n$ (structure of the classification change and the categories intersect each other) with axb where a is the cardinality of the ICD-10 codes and b is the cardinality of ICD-11 codes.

2. Methods

For this analysis the 2019 decision tables are considered, since they include the most recent ICD-10 updates. The most represented rule is the DUETO, with more than 27 million records (90.1% of the total rules). The analysis thus focused on the DUETO rules. These rules represent the vast majority of the rules and are the most critical for coding.

2.1. Translation method

From former evaluations of the transition between the ICD-9 and ICD-10, it is known that the transition to ICD-11 will have an impact and the mapping will not be enough to completely automate the transition. The mapping table gives the possibility to translate single codes, but when it comes to the rules, we need to translate relationships between codes. Due to the relation between the pair elements, we cannot translate codes separately, but we need to interpret the relation from a logical point of view and the impact that the diverse mapping cardinality has on the two codes involved.

2.2. DUETO rule-type translation

The *DUETO* relation can shortly be described as:

Code A DUETO B if B is an acceptable cause of A (according to ICD provisions); in IRIS terminology, A is called codeDef and B is called subcodeDef.

The goal of the translation is to identify all the possible translation rules that can be automated. Afterwards we define the *DUETO* rule-type in combination with the mapping cardinality of the two codes that can be automated, and which needs expertise support.

The decision tables are based on pair of codes, but since the *DUETO* rules may include many consecutive pairs, the conditions can be represented also as ranges of codes. Using ranges, it is possible to achieve better results but also to reuse part of the translation of the *subcodeDef*.

Given a rule, the basic idea is to verify whether a mapping exists between single codes for both *codeDef* and *subcodeDef* and of which kind. A rule can be translated automatically if both sides can be translated automatically. In some cases, we may need a different translation of codes for *codeDef* and *subcodeDef*, since the consequences of the rule-type could be different. So we want to always suggest the translation codes based on the mapping but, basing on the mapping type and the implications of the relation, the system also suggest which are the codes that can be accepted or need expert supervision.

Since the disease knowledge evolves, some ICD-10 codes may have no mappings to the ICD-11 classification since the concept is no longer used, or ICD-11 codes may have no mapping from the ICD-10 since they are new. Those codes are problematic and need expert supervision. Sometimes, using ranges for the translation, some of those codes could be handled. Since the classification is hierarchical, translating the higher levels could avoid manual intervention on some of the terminal codes with no mapping, since the results would be covered by the parent translation.

AUTOMATED TRANSLATION

TRANSLATION WITH EXPERT INTERVENTION

Figure 1. Summary of translation cases.

3. Results

Basing on the cardinality of the mappings on both sides, we can distinguish between manual and automatic translations.

The equivalent mapping ($1x1$), when found on both sides of the rule, is the basic case of automation, applicable to all the rule types. On the other side, when a mapping with cardinality of nxn is present, translation will always be manual. Rules where mapping of type $nx1$ and $1xn$ appear are those that provide some chance of automated translation, as depicted in Figure 1.

The key for the DUETO rule translation is to remember that is not representing causality, but the possibility of causality. Thus, whenever aggregated conditions are present in the ICD-11 translation, such causality could not be excluded and thus the mapped rule is valid as obtained from the mappings. Let’s examine two examples of automated translation in table 1.

Table 1. Automated translation examples.

case	ICD-10 rule	Mappings involved	ICD-11 rule
(a)	A01.0 (Typhoid fever) DUETO C33 (Malignant neoplasm of trachea)	A01.0 \equiv 1A07 C33 \equiv 2C24	1A07 (Typhoid fever) DUETO 2C24 (Malignant neoplasms of trachea)
(b)	F03 (Unspecified dementia) DUETO R54 (Senility) <i>But also:</i> F01 (Vascular dementia) DUETO R54 (Senility)	F03 \sqsubseteq 6D8Z R54 \equiv MG2A <i>But also:</i> F00 (Dementia in Alzheimer disease) \sqsubseteq 6D8Z F01 (Vascular dementia) \sqsubseteq 6D8Z	6D8Z (Dementia, unknown or unspecified cause) DUETO MG2A (Old age)
(c)	J96.9 (Respiratory failure, unspecified) DUETO F03	J96.9 \equiv CB41.2 F03 \sqsubseteq 6D8Z <i>But also:</i> F00 \sqsubseteq 6D8Z F01 \sqsubseteq 6D8Z	CB41.2 (Respiratory failure, unspecified as acute or chronic) DUETO 6D8Z

Let’s now examine the cases that need expert intervention in table 2. In this case, since ICD-11 conditions are recorded with greater detail, we cannot ensure all of them are reasonably part of a DUETO rule (but the expert will know and decide). No example is provided for mixed situations involving nxn because too complex to be shown here.

Table 2. Examples of rules translation needing expert intervention.

case	ICD-10 rule	Mappings	ICD-11 rule
(d)	I46.9 (Cardiac arrest, unspecified) DUETO R26.3 (Immobility)	I46.9 \supseteq MC82 (Cardiac arrest) I46.9 \supseteq MC82.0 (Ventricular tachycardia and fibrillation cardiac arrest) I46.9 \supseteq MC82.1 (Bradycardic cardiac arrest) I46.9 \supseteq MC82.2 (Asystolic cardiac arrest) I46.9 \supseteq MC82.3 (Cardiac arrest with pulseless electrical activity) R26.3 (Immobility) \equiv MB44.3 (Immobility)	We cannot ensure that all types of cardiac arrest can be due to immobility
(e)	I27.9 (Pulmonary heart disease, unspecified) DUETO B44.1 (Other pulmonary aspergillosis)	I27.9 \equiv BB0Z (Pulmonary heart disease or diseases of pulmonary circulation, unspecified) B44.1 \supseteq CA82.4 (Aspergillus-induced allergic or hypersensitivity conditions) B44.1 \supseteq 1F20.12 Chronic pulmonary aspergillosis)	We cannot ensure that both CA82.4 and 1F20.12 can cause Pulmonary heart disease.

In cases like (d) and (e), the expert should be given the list of mappings that map to the same ICD-11 entity, to let him decide which ones generate valid DUETO rules.

Using this method for the translation the expert has a tool to quickly get an overview of the suggestions for the translation, but also has the possibility to focus more on the results that are suggested as manual after the validation of the method.

CodeDef and *subcodeDef* can be translated separately, and for the translation of the *subcodeDef* we can reuse the same translation in different rules. A further improvement is the translation reuse of a sub-range, that can be used for the translation of ranges that incorporate the translated range. Both techniques help in reducing human intervention.

Further details on the translation methodology can be found in [5].

By exploring the distribution of mapping types in the coding rules, we evaluated in about 3.2 million pairs those needing manual intervention, out of about 27 millions. With the reuse of the validated range translation we estimated a relevant reduction, where the cases that still need manual support are about 87000 codes (considering manual translation of *codeDef* and *subcodeDef*).

3.1. Prototype

The prototype is aimed at providing decision support in the translation of mortality rules from ICD-10 to ICD-11. For the implementation, we choose a web-based model where experts can work collaboratively from a different location but also for the consistency of the results. It has a full implementation of the visualization and editing of the “DUETO” translation rules of the decision tables. Rules are grouped where possible with the same *subcodeDef* to ease the translation and facilitate maintenance over time.

4. Conclusion

The presented method and prototype seem suitable for supporting the process of transition of Iris from ICD-10 to ICD-11, however it further needs expert validation to correctly estimate the workload needed. Adaption of results obtained on the DUETO rules is being carried out for the other rules, in particular those describing direct sequels of conditions.

Machine Learning Assisted Citation Screening for Systematic Reviews

Anjani DHRANGADHARIYA^{a1}, Roger HILFIKER^b, Roger SCHAER^a and Henning MÜLLER^{a,c}

^a *University of Applied Sciences Western Switzerland (HES-SO), Sierre, Switzerland*

^b *School of Health Sciences, HES-SO Valais-Wallis, Leukerbad, Switzerland*

^c *University of Geneva (UNIGE), Geneva, Switzerland*

Abstract. Evidence-based practice is highly dependent upon up-to-date systematic reviews (SR) for decision making. However, conducting and updating systematic reviews, especially the citation screening for identification of relevant studies, requires much human work and is therefore expensive. Automating citation screening using machine learning (ML) based approaches can reduce cost and labor. Machine learning has been applied to automate citation screening but not for the SRs with very narrow research questions. This paper reports the results and observations for an ongoing research that aims to automate citation screening for SRs with narrow research questions using machine learning. The research also sheds light on the problem of class imbalance and class overlap on the performance of ML classifiers when applied to SRs with narrow research questions.

Keywords. Systematic reviews, Automation, Natural language processing, Machine learning

1. Introduction

Summarizing evidence in a specific domain through the process of conducting systematic reviews (SR) becomes increasingly difficult with an exponential increase in the number of primary research publications and an increasing variety of publishers. With this increased publication rate, citation screening for conducting the SRs has become time-consuming and labour intensive. The core of citation screening involves manually categorizing the studies found in literature search into relevant or non-relevant depending upon predefined criteria for the research question at hand [1]. This screening is usually performed by two independent reviewers, who often cannot keep up with the manual process of screening the studies and constantly updating outdated SRs [2].

In the area of physiotherapy and rehabilitation such an exponential increase in the number of publications is also observed². For an ongoing review on exercise and non-exercise interventions in reducing cancer-related fatigue retrieved over 30,000 references, about 2,000 of which were published in 2017 alone. It took more than 200 hours for each of the two independent reviewers to manually assess the titles and abstracts

² [https://www.ncbi.nlm.nih.gov/pubmed?term=\(physiotherapy\)%20OR%20rehabilitation](https://www.ncbi.nlm.nih.gov/pubmed?term=(physiotherapy)%20OR%20rehabilitation)

for relevance to the research question before the studies were taken for further meta-analysis [3]. Supervised machine learning based classification approaches are successfully applied for automation of citation screening but either only for broad and shallow SRs [4] or SRs that retrieved fewer than 6,000 studies [5]. However, there are SRs that address very specific research questions leading to narrow, predefined criteria for selection of relevant studies to be included for meta-analysis. For such narrow SRs, inclusion prevalence becomes as low as 10%, which means that out of all the studies retrieved during the search phase, 90% are excluded as non-relevant. A narrow research question combined with a low inclusion prevalence leads to class imbalance and class overlap problems for classification tasks that generally reduce classifier performance [6]. Class overlap cannot be artificially controlled but class imbalance can be tackled using oversampling or undersampling [7]. In this work, we aim to explore machine learning and natural language processing to assist citation screening in SRs with a narrow research question and low inclusion prevalence using word embeddings and random oversampling.

2. Methods

2.1 Datasets

Data sets from the open access literature were used in the work is described below.

- a) *Word embedding* Titles and abstracts (TA) of 2.09 million studies included in the PubMed Central Open-Access subset (PMC-OA) were used to generate semantic word embedding using the two most common architectures: word2vec and fastText [8,9].
- b) *Data for the screening process* The data set used to test automation approaches included the studies identified for citation screening in an update to the systematic review by Hilfiker *et al.* [3]. The data set included TA from 31,279 studies identified during the search phase of this SR. These studies were already manually assessed for relevance and labelled by two reviewers into two mutually exclusive labels. 4,066 studies assessed as relevant were labelled “include” and the rest were labelled “exclude”. The inclusion prevalence for this case is only about 13% leading to class imbalance.

2.2 Screening Automation

To automate the screening and explore the effect of class imbalance, six supervised binary classifiers were trained to classify documents into “include” (relevant) vs. “exclude” (non-relevant) using the data set of Section 2.1 represented using corpus-specific static word embedding. This approach follows steps enumerated below.

1. *Word embedding generation* To generate embedding, the PMC-OA data were lower-cased and all punctuation except the hyphens were removed. Phrase generation was then performed using the word2phrase tool³ to identify frequently occurring bi-grams. The output of phrase generation along with the unigrams was fed to gensim’s word2vec⁴ and to fastText⁵ using the

³<https://github.com/travisbrady/word2phrase>

⁴<https://radimrehurek.com/gensim/models/word2vec.html>

hyperparameters in Table 1 to obtain two dense, semantic, real-valued word embeddings [10].

Parameter	Value	Parameter	value	Parameter	value
Size	300	Alpha	0.05	bucket*	2000000
Window	5	min alpha	0.0001	minn*	3
min eount	5	sample	0.0001	maxn*	6
sg	1	iter/ epoch	5	seed	1
hs	1	negative	5		

Table 1. Hyperparameter values used to generate word embeddings using gensim’s word2vec and the fastText functionality. (*) means that these parameters were available only for the fastText embeddings.

2. *Data set for text pre-processing* Post deduplication and removal of non-English language studies led to 25,540 studies remaining. For these remaining studies, the text was lower-cased and tokenized into words using NLTK (Natural Language ToolKit). Irrelevant tokens were removed using a predefined set of stop-words provided by NLTK and PubMed. Additional corpus-specific stop-words identified during the experiments with the training set were removed accordingly. The text normalization process converted British English terms into American English. After token lemmatization, a corpus vocabulary was constructed from all the unique unigram and bigram tokens. To scale this vocabulary down, uninformative short tokens with fewer than five characters and the tokens with vocabulary count lower than five were removed assuming they were not representative of the classes.
3. *Random oversampling* Class imbalance often deteriorates the classifier performance, so in the present data set it was addressed using naive random oversampling. This method randomly duplicates data points from the minority class and brings the total number of instances in the minority class equal to the majority class [6].
4. *Feature extraction* Feature extraction was performed to generate real-valued, dense feature vectors from text. These features were used as input to train the supervised ML classifiers. For non-neural ML classifiers, from each of the 25,540 studies word vectors were extracted for each token using both generated word embeddings. All vectors for each token in the individual study were averaged over the entire study normalized by study length to produce a single 300-dimensional vector representing a particular study. For the Convolutional Neural Network (CNN), feature extraction was part of the model, where a static, non-trainable weight matrix generated from the word embedding was provided with the embedding layer to extract token word vectors during training.
5. *Classifier training and evaluation* Six classifiers including Logistic Regression (LR), Support Vector Machines (SVM), k-nearest neighbor (KNN), Decision Trees-CART (DT), Random Forest (RF), and CNNs were trained and evaluated over the generated text feature to perform binary classification. Hyperparameter tuning was performed using GridSearch. A CNN was trained using hyperparameters loosely based on suggestions from Zhang *et al.* [11]. Classifier performance before and after oversampling was evaluated on an unseen validation data set and metrics pertinent to imbalanced classification

⁵ <https://radimrehurek.com/gensim/models/fasttext.html>

like precision, recall, F1 and precision-recall AUC (PR-AUC) score were tracked[7].

Figure 1. A t-SNE projection for 25,540 studies labelled “include” vs. “exclude” before and after oversampling.

3. Results and Discussion

The data set used for training and evaluating the classifiers comprised 2,259 relevant studies labelled “include” and 23,281 labelled “exclude”. Cosine similarity between class centroid vectors for the “include” and “exclude” classes before and after oversampling is 0.985814 and 0.985824 respectively. A high cosine similarity is indicative of high class overlap even after tackling the class imbalance using oversampling (see Figure 1).

The results obtained by applying classifiers on the data set before and after random oversampling are summarized in Table 2 and 3. Before oversampling, the classifiers focused on improving the performance for the majority class but in reality they are simply predicting the majority class as noticeable from the relatively high F1 score for the exclude class. Upon oversampling, the overall classifier performance drastically improves for the minority class especially the precision (see Table 3), while the precision for the majority class is reduced with a small improvement in recall.

Times ne	embedding	Class “include”				Class “exclude”		
		Precision	Recall	F1	PR-AUC	Precision	Recall	F1
LR	fastText	0.4044	0.8990	0.5576	0.6008	0.9891	0.8746	0.9283
SVM	fastText	0.6538	0.4640	0.5428	0.6317	0.9463	0.9746	0.9602
KNN	word2vec	0.6536	0.6066	0.6288	0.6512	0.9619	0.9685	0.9652
DT	fastText	0.2961	0.8627	0.4394	0.4287	0.9837	0.8000	0.8821
RF	fastText	0.4995	0.7892	0.6108	0.5921	0.9780	0.9209	0.9485
CNN	fastText	0.6545	0.5032	0.5690	0.6388	0.9511	0.9732	0.9620

Table 2. Classifier performance before random oversampling for the “include” and “exclude” classes

If the task is considered a classification task, a high class overlap still leads to unacceptable precision and recall values for citation screening implying the inclusion of false-positive studies and exclusion of false-negative studies. Our future work has two directions: Firstly, experimenting with systematic oversampling techniques like Synthetic Minority Over-Sampling Technique (SMOTE) and Adaptive Synthetic (ADASYN) and considering this task as data extraction rather than classification [12].

Classifier	embedding	Class “include”				Class “exclude”		
		Precision	Recall	F1	PR-AUC	Precision	Recall	F1
LR	word2vec	0.8981	0.8850	0.9116	0.9342	0.8951	0.9090	0.8816
SVM	fastText	0.8914	0.8818	0.9012	0.9378	0.8990	0.8792	0.8890
KNN	word2vec	0.8860	0.8303	0.9500	0.9321	0.9418	0.8055	0.8682
DT	fastText	0.8348	0.8201	0.8510	0.8734	0.8285	0.8463	0.8126
RF	word2vec	0.8695	0.8918	0.8488	0.9279	0.8966	0.8757	0.8560
CNN	word2vec	0.9034	0.7480	0.8183	0.9318	0.7850	0.9200	0.8471

Table 3. Classifier performance after random oversampling for the “include” and “exclude” classes.

4. Conclusion

To the best of our knowledge, this is the first attempt to explore citation screening automation for a narrow systematic review topic using domain-specific word embedding on a range of ML classifiers. The research specifically sheds light on the impact of class imbalance and class overlap on the classifier performance before and after oversampling as also discussed by [6,7]. Knowledge of these challenges is useful for further development of automation approaches for citation screening.

Abstract. Machine Learning (ML) can improve the diagnosis, treatment decisions, and understanding of cancer. However, the low explainability of how “black box” ML methods produce their output hinders their clinical adoption. In this paper, we used data from the Netherlands Cancer Registry to generate a ML-based model to predict 10-year overall survival of breast cancer patients. Then, we used Local Interpretable Model-Agnostic Explanations (LIME) and SHapley Additive exPlanations (SHAP) to interpret the model’s predictions. We found that, overall, LIME and SHAP tend to be consistent when explaining the contribution of different features. Nevertheless, the feature ranges where they have a mismatch can also be of interest, since they can help us identifying “turning points” where features go from favoring *survived* to favoring *deceased* (or vice versa). Explainability techniques can pave the way for better acceptance of ML techniques. However, their evaluation and translation to real-life scenarios need to be researched further.

Keywords. Artificial Intelligence, interpretability, oncology, prediction model

1. Introduction

Although it has been shown that Machine Learning (ML) methods are able to predict oncological outcomes [1], there are still a few factors that hinder their widespread clinical adoption. One of these factors is the lack of trust in the models. Often, ML tools are considered black boxes. If decisions need to be made that are based (at least partially) on predictions made by ML algorithms, users need to be able to understand how and why the algorithm has come up with that decision [2].

In the last couple of years, ML explainability has gained considerable interest. Recently, two techniques have been proposed and developed to make ML models more interpretable: Local Interpretable Model-Agnostic Explanations (LIME) [3] and SHapley Additive exPlanations (SHAP) [4]. However, evaluation of these tools remains relatively unexplored. Although some studies have attempted to evaluate explanations of

¹Corresponding author: Arturo Moncada-Torres; Zernikestraat 29, 5612 HZ Eindhoven, NL;
E-mail: a.moncadatorres@iknl.nl.

model predictions by letting users test which explanations are more understandable or intuitive [5], more analytical, standardized evaluations are needed.

In this paper, we used data from the Netherlands Cancer Registry (NCR) to generate a predictive model of 10-year overall survival (OS) after curative breast cancer surgery. Then, we applied LIME and SHAP to the obtained model to explain its predictions. Finally, we evaluated said interpretability methods by analysing their explanations and the agreement between them, which allowed us to identify features' turning points.

2. Materials & Methods

We used NCR data granted under data request K18.999. It consisted of demographic, clinical, and pathological data of patients in the Netherlands diagnosed between 2005 and 2008 with non-metastatic breast cancer who underwent surgery. Features included age, tumor characteristics, hormonal receptor statuses, clinical and pathological TNM-staging, and number of removed and positive lymph nodes. We imputed missing values using Deep Learning and K-Nearest Neighbor (KNN). We defined 10-year OS as the target variable for our model. The final dataset consisted of 46,284 patients and 31 features.

We performed feature selection using a combination of 21 different filter and wrapper methods. Each of them output a ranking ordering feature predictiveness. Then, we computed the median of these rankings and chose the six best ranked features: 1. *age*, 2. ratio between the number of positive and removed lymph nodes (*ratly*), 3. number of removed lymph nodes (*rly*), 4. tumor size in millimeters (*ptmm*), 5. pathological TNM stage (*pts*), and 6. tumor grade (*grd*).

We experimented with a variety of ML tools: Random Forest, Extreme Gradient Boosting (XGB), KNN, Artificial Neural Networks, Naïve Bayes, and Logistic Regression. We performed a randomized grid search to train, test, and optimize each of them. Since our target variable had a class distribution of roughly 75% (*survived*) versus 25% (*deceased*), we used stratified 10-fold cross-validation to optimize the models' hyperparameters. Then, we evaluated their performance using the Area under the Curve (AUC) as a metric, with XGB yielding the highest value (0.78). Therefore, we used XGB for the rest of this study.

In order to better understand the model's predictions, we used LIME and SHAP. On the one hand, LIME approximates *individual predictions* of a (black box) model with a *local* (interpretable) surrogate model that is as close as possible to the original one. Explanations are produced by minimizing a loss function between the predictions of both of them. The complexity of the surrogate model is used to explain the original model [3]. On the other hand, besides offering local interpretability, SHAP allows to explain a model *globally* by expressing it as linear functions of features [4]. In other words, it explains how much the presence of a feature contributes to the model's *overall predictions*.

To assess the consistency of LIME in explaining individual predictions, we applied it to each of the predictions of the test set (20% of the data) 100 times. We defined consistency when LIME assigned values with the same sign in all cases. Then, we evaluated global variable importance using SHAP. Finally, we tested agreement between LIME and SHAP values by comparing their instances (i.e., local) explanations in the test set. We defined agreement when both methods assigned either a positive or a negative contribution to the same feature of the same data instance.

3. Results

Figure 1 shows five representative data instances (i.e., patients) picked at random of the LIME consistency test. The x -axis shows the values for a particular feature, while the y -axis denotes the feature weight assigned to that value by LIME. A positive weight means it contributed to *survived*, while a negative one contributed to *deceased*. Across all plots, the position of each box is the same for each patient. For instance, the first box of each plot corresponds to the same patient, who was 51 years old, had a *ratly* value of 0, a *rly* value of 1, etc. LIME was consistent in >98% of the cases of *age*, *pts*, and *grd*. However, for *ratly*, *rly*, and *ptmm* LIME was consistent in 74%, 8%, and 55% of the cases, respectively. These cases correspond to the boxes in Figure 1 that cross 0 (dotted line), which means that LIME yielded contradictory weights.

Figure 2 shows the SHAP values of the six features used by the global model. The x -axis shows the SHAP values that correspond to the features shown on the y -axis. The color scale indicates the feature values, which range from low (blue) to high (red). Similarly to LIME, a positive SHAP value contributes to *survived*, while a negative one contributes to *deceased*.

Figure 1. LIME consistency of five representative data instances (i.e., patients) picked at random. Contradictory explanations correspond to boxes that cross the dotted line at 0. Practically, *age*, *pts*, and *grd* had consistent LIME values, while the opposite can be said for *ratly*, *rly*, and *ptmm*.

The percentage of instances where LIME and SHAP agreed on their explanations for each feature was as follows: *age*, 97.5%; *ratly*, 95.9%; *rly*, 87.8%; *ptmm*, 91.9%; *pts*, 99.6%; *grd*, 99.9%. Figure 3 shows the individual feature weights for *age* (since it was the best-ranked feature) and for *rly* (since it was the feature with the largest disagreement). The x -axis denotes the feature values, while the y -axis denotes the feature weights assigned by the interpretability methods. Circles indicate an agreement between them, while crosses indicate the opposite.

Figure 2. Summary plot of all SHAP values. Globally, *age* has the biggest impact on the model output.

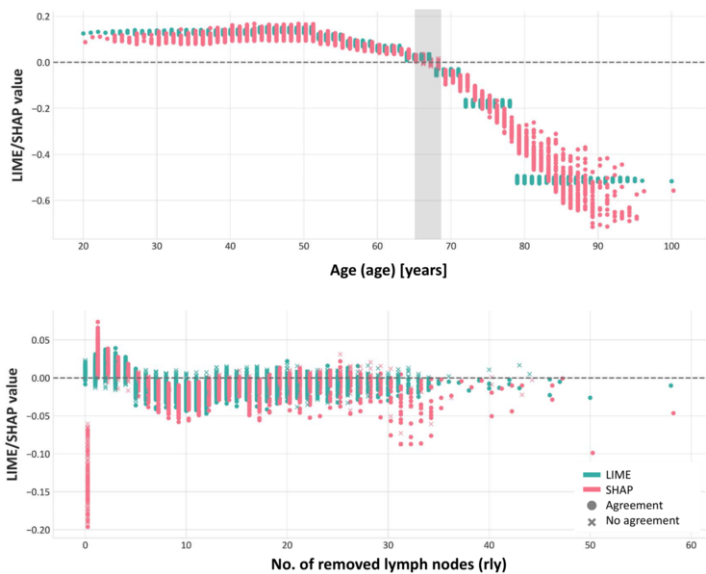

Figure 3. Feature weights assigned by LIME and SHAP to all test set instances for *age* and *rly*. The shaded area shows clear *age*’s clear “turning point”. SHAP markers were shifted slightly along the x-axis for clarity.

4. Discussion

Figure 1 shows that LIME tends to assign consistent values to categorical features. For example, a *pts* of 1 is assigned almost identical feature weights in different patients. A similar thing occurs for a *grad* of 2. However, LIME has more difficulties with numerical features. For instance, there is very little difference in the impact that having 1 or 16 lymph nodes removed has on the model predictions. We think this is because LIME discretizes continuous features by binning them and treating them as categorical, losing information. Figure 1 also shows that LIME weights can be contradictory. For example, in the *rly* case, LIME values for the same patient are often inconsistent. It has been suggested that LIME’s uncertainty can be explained by randomness in the sampling procedure and the variation of interpretation quality across different data instances [6], which is in line with the presented results.

Figure 2 combines the features' effects (x-axis) with their importance (y-axis). At a global level, *age* is the most important feature, while *rly* is the least important. This could be explained by its non-monotonic behaviour (i.e., low *rly* values are assigned positive and negative weights).

Although LIME and SHAP values show a similar trend overall for both *age* and *rly* (Figure 3), we can also distinguish specific regions of mismatch. These are of particular interest, since they can help us identify "turning points" in the features' values. For example, in the case of *age*, mismatches occur approximately between 65 and 68 years (shaded area). This could explain where the model considers *age* to contribute towards *survived* or towards *deceased*.

5. Conclusion

In this study, we used breast cancer data from the NCR to generate an XGB-based model for predicting 10-year OS. We explained the model's predictions using LIME and SHAP and compared their performance. In few cases, LIME showed inconsistent and contradictory explanations of individual predictions. Furthermore, comparing LIME and SHAP showed agreement between them in 95.4% of the instances. The regions of mismatch allowed us to identify "turning points" in the features' values, which indicate where features go from favoring *survived* to favoring *deceased* (or vice versa).

Methods like LIME and SHAP are a first step to provide a more interpretable way of explaining complex models than what the models are capable of themselves. It is important to keep in mind that perfect explanations are also infeasible, since there is no gold standard to which the explanations can be compared. This also makes the evaluation of these methods a challenge. These type of methods pave the way for larger use and acceptance of ML techniques for digital health applications. However, their evaluation and translation to different fields need to be researched further.

^b*HES-SO / HEG, Information Sciences, Geneva, Switzerland*

^c*Information Systems Department, University Hospitals of Geneva (HUG), Geneva, Switzerland*

Abstract. The encoding of Electronic Medical Records is a complex and time-consuming task. We report on a machine learning model for proposing diagnoses and procedures codes, from a large realistic dataset of 245 000 electronic medical records at the University Hospitals of Geneva. Our study particularly focuses on the impact of training data quantity on the model's performances. We show that the performances of the models do not increase while encoded instances from previous years are exploited for learning data. Furthermore, supervised models are shown to be highly perishable: we show a potential drop in performances of around -10% per year. Consequently, great and constant care must be exercised for designing and updating the content of such knowledge bases exploited by machine learning.

Keywords. Medical coding, machine learning, text mining.

1. Introduction

The coding, or encoding, of medical records with standard classifications serves multiple purposes for healthcare actors, including billing and reimbursement, quality control, epidemiological surveillance, or cohort identification for clinical trials [1,2]. This task is usually performed by professional coders, at the term of an episode of care (EOC). These coders have to master knowledge in the field of medicine, along with the handling of large code sets, coding rules and local guidelines [3]. For these reasons, manual coding is expensive and time-consuming. The amount of available electronic medical records (EMRs), potentially exploitable by computers, has steadily grown in recent years [4]. Hence, machine learning algorithms are today likely to produce accurate and effective tools for assisting human coders [5].

We report on the development and evaluation of a machine learning – or supervised – model for suggesting codes, from a large dataset of EMRs.

A citation attributed to Peter Norvig, Google's Chief Scientist, claims that "more data beats clever algorithms" [6]. Several reported works on text categorization tend to support this idea, and incite to direct efforts towards increasing the size of annotated

¹ Corresponding Author, SIB Swiss Institute of Bioinformatics, quartier Sorge - bâtiment Amphipôle, 1015 Lausanne, Switzerland; E-mail: julien.gobeill@sib.swiss.

learning collections [7,8]. Our study has particularly focused on the impact of exploiting growing amounts of learning data on the algorithm's performances. The figure below illustrates the global workflow of the automatic encoding process.

Figure 1. Global workflow of the machine learning encoding. The input is all textual documents from an EOC. The algorithm compares it with past coded episodes contained in the Knowledge Base, and retrieves the k most similar instances, based on statistical textual similarity. From the encoding of these similar episodes, the algorithm infers rankings of candidate CIM and CHOP codes, along with probability scores.

Our study was conducted in the University Hospitals of Geneva (HUG), with a real dataset ranging from 2011 to early 2016 (245 000 EOCs). In Switzerland, EOCs are encoded with two medical classifications derived from the International Classification of Diseases (ICD). Diagnoses are encoded with the CIM classification, issued from ICD-10, German modification; procedures are encoded with the CHOP classification, issued from the ICD-9-CM in 2008 but having evolved since. In Switzerland, both classifications are available in German, French and Italian, but all medical records in Geneva are written in French.

This encoding task is a multi-label automatic text categorization problem [9]. Most reported systems in the literature rely on the popular Support-Vector Machines (SVM). Yet, for large multi-label categorization, SVM has been reported to scale with difficulties [10], requiring the usage of data reduction or feature selection [1]. In our study, with our objectives, we chose to exploit a simple, yet powerful classification algorithm: the k -Nearest Neighbors (k -NN). From a Knowledge Base (KB) containing past encoded instances, this algorithm retrieves the instances that are the most similar to a new instance, and assigns to it the most common codes among these neighbors.

2. Data

At the HUG, encoding is performed by professional coders after an EOC. Coders have limited contacts with the healthcare personnel, but they review all produced documents. There are 4 318 different types of documents, including admission notes, exam or operative reports, progress notes, or discharge letters. Coders have to detect disorders that were addressed during the EOC, and to encode them into CIM codes. For example, for a patient admitted for an alcoholic cirrhosis of liver, the episode will be encoded with the CIM code K70.3 “Cirrhose alcoolique du foie”. The coders also have to detect procedures that were performed. In our example, if a liver biopsy was performed, the coder has to encode it with the CHOP code 50.13.10 “Biopsie du foie transveineuse”. Thus, the whole dataset consists in 245 000 encoded EOCs, from 2011 to early 2016. It is worth noting that what is encoded is EOCs, not documents. In this perspective, all experiments were conducted at the EOC level. For each experiment, a test set of

randomly selected 250 EOCs was submitted to the tool. The algorithm is judged on its capacity to output the codes that were effectively assigned to these episodes by professional coders.

3. Methods

The investigated algorithm is a k-Nearest Neighbors (k-NN). This algorithm performs instance-based learning; it does not learn any discriminative function, but rather exploits a Knowledge Base (KB), containing previously labelled instances, in order to infer real-time decisions [10]. For such text categorization problems with numerous and multiple labels, k-NN has been reported to efficiently scale and to perform comparably with Support Vector Machines [11].

In this study, the KB contains previously encoded EOCs. A similar search engine is designed for retrieving nearest neighbors (i.e. EOCs), based on textual similarity. The Terrier information retrieval platform was used for this purpose [12]. The k parameter sets the number of neighbors exploited for making decisions. Once similar EOCs are retrieved, the second step of the k-NN is to infer encoding for the input episode. For this purpose, the algorithm simply computes what are predominant codes among the retrieved learning instances. The algorithm hence outputs ranked lists of disorders (CIM) and procedures (CHOP) codes, along with confidence scores.

The algorithm is judged on its capacity to output the codes that were effectively assigned to these episodes by professional coders. The evaluation relies on metrics issued from information retrieval [13]. As the tool potentially outputs hundreds of codes – along with decreasing scores – evaluated lists are limited to the top 10 predicted codes. In a semi-automatic workflow, ten is a convenient number of codes easily checkable by the coder. Hence, the recall at rank 10 curves presented in the Results section is the proportion of actual codes that were outputted by the tool in the top 10 ranks. Precision curves are not presented for clarity concerns, but show similar shapes.

4. Results

Preliminary studies (not reported) were conducted with a dataset limited to 2014 EOCs. For both disorders and procedures, the performances of the tool increased with the size of the KB. The most promising observation is that more data leads to better results: for 2014 EOCs, when the size of the KB doubles, the recall is improved by approximately 10%. Thus, with the complete dataset (2011 - 2016), higher performances were expected.

Figure 2. Performances (Recall at rank 10) of the encoding with 2015 queries, for disorders (CIM codes) and procedures (CHOP codes), depending on the k parameter. The KB is populated by previously encoded EOCs, from 52 000 for 2015 only, to 230 000 for the 2011 to 2015 range.

A first set of experiments was conducted for assessing the impact of training data quantity on the model's performances (Figure 2). The test set was a sample of EOCs from 2015, while we progressively increased the number of past EOCs for populating the KB. For both disorders and procedures, all curves are interwoven: the performances of the model do not increase while encoded EOCs from previous years are injected in the KB – yet the past EOCs do not damage the model.

Figure 3. Performances (Recall at rank 10) of the encoding with 2015 KB, depending on the k parameter. Different test sets, containing EOCs sampled in a single year ranging from 2011 to 2016, were used.

A second set of experiments focused on the durability of the model (Figure 3). This time, the KB did not vary and only contained 50 000 encoded episodes from 2015. The model was evaluated with different test sets, each sampled in a single year ranging from 2011 to 2016. The different curves are this time remarkably distinct. With a KB containing previously encoded EOCs from 2015, the best results are reached for input EOCs from 2014 and 2015. Older episodes, from 2013 to 2011, obtain progressively weaker results. These results show that the encoding is considerably year-dependent, and suggest that a model built on a single year is highly perishable – with a potential drop in performances of around -10% per year.

Table 1. Final performances reached for KB and queries from 2015. F-measure is the harmonic mean of precision and recall. This study focused on optimizing recall values.

Coding	F1 at rank 10	P at rank 10	R at rank 10	R at rank 20
Diagnoses	39 %	32 %	51 %	62 %
Procedures	29 %	18 %	72 %	78 %

5. Discussion

The F-measure at rank 10 reached by the tool for 2015 data is 39.3% (see Table 1). This is competitive with F-measures (39.5% [14], 42% [5]) reported in other studies dealing with such large-scale data. Beyond state-of-the-art comparisons, the recall values – 62% for diagnoses and 78% for procedures at rank 20 – must be considered in the light of the inter-annotator agreement, which is a theoretical upper bound. In 2006, this agreement was reported about 79% in the University Hospitals of Geneva [15].

However, the results indicate that the performances of the machine learning model are considerably year-dependent. This could be explained by two main reasons. First, the classifications used for medical encoding in Switzerland evolve over time: every two years for diagnoses, every year for procedures. Codes can be created, merged, or migrated. Second, the coding guidelines proper to each hospital also evolve over time.

Indeed, on the top of diagnoses and procedures codes, rules defining reimbursement are applied by Swiss authorities based on DRGs (Diagnosis Related Groups), unknown from facilities. As two different accurate encodings of the same EOC can lead to differences in the reimbursement, each facility aims at continuously improving its proper coding guidelines, in order to better encode provided healthcare. The consequence is a typical case of concept drift in medical encoding.

6. Conclusion

Are more data better for automatic encoding of EMRs by machine learning? In University Hospitals of Geneva, the answer is mixed. For a unique year, injecting more data in the knowledge base leads to progressively better performances for the algorithm. Yet, injecting encoded episodes from past years does not improve – while does not harm – the performances. Another essential result is that KBs are considerably year-dependent, and a model built on previous years' EOCs appear to be perishable. In this study, a potential drop in performances of around -10% per year has been brought to light. Consequently, great and constant care must be exercised for designing and updating the content of such knowledge bases exploited by machine learning. As Peter Norvig has refined: “More data beats clever algorithms, but better data beats more data”.

^bCHUV, Switzerland

Abstract. Medical studies are usually time consuming, cumbersome and extremely costly to perform, and for exploratory research, their results are also difficult to predict a priori. This is particularly the case for rare diseases, for which finding enough patients is difficult and usually requires an international-scale research. In this case, the process can be even more difficult due to the heterogeneity of data-protection regulations, making the data sharing process particularly hard.

In this short paper, we propose MedCo² (pronounced *MedCo square*), a distributed system that streamlines the process of a medical study by bridging and enabling both data discovery and data analysis among multiple databases, while protecting data confidentiality and patients' privacy. MedCo² relies on interactive protocols, homomorphic encryption and differential privacy. It enables the privacy-preserving computations of multiple statistics such as cosine similarity and variance, and the training of machine learning models, on patients that are obliviously selected according to specific criteria among multiple databases.

Keywords. data discovery, data analysis, privacy, confidentiality, homomorphic encryption

1. Introduction

The current trend towards personalized medicine requires researchers to access increasingly larger cohorts of subjects [1], the size of which often exceeds the amount of data available at the researchers' facility. This results in an urgent need for efficient and automatic data sharing mechanisms between medical institutions. Medical data, however, are particularly sensitive, and attempting to share them poses significant threats to the subjects' privacy, as it increases the risk of leaks to ill-intentioned persons or organizations. Medical institutions often refrain from sharing their data due to the increasing number of breaches [2,3], and to their derived reputation and financial implications [4]. Finally, national and international regulations (e.g., HIPAA [5] in the U.S. and the GDPR [6] in the E.U.) impose strong requirements in terms of both confidentiality and restriction of data access that are commonly not met by the existing sharing-solutions [7]. In this environment, in order to access the data, researchers are faced with complex challenges throughout the whole process. Cohort exploration is usually the first step of a medical study; when performed across several medical institutions, it becomes very difficult, as obtaining the necessary legal authorizations and signing agreements between institutions

can take months. This becomes almost impossible when hospitals are in different countries because of the incompatibility of national legal frameworks. Finally, researchers can be left with data of limited value to perform the desired analyses, as they cannot get a priori information (e.g., size, availability and statistical properties such as distribution or moments) to assess the suitability of the data before actually gaining access to them. We propose MedCo², a novel system featuring privacy-preserving cohort exploration and advanced cohort analysis. It enables a researcher to assess the presence of subjects with specific traits and features, compute statistics, and/or train and evaluate machine-learning models on subjects' records, over distributed databases. By relying on distributed and interactive protocols, homomorphic encryption and differential privacy, our system ensures that these queries can be executed yet still protect the confidentiality of data and the privacy of subjects. Finally, MedCo² distributes the trust and avoids single points of failure, as both the storage and the computations are distributed among multiple nodes.

2. System and Threat Models

MedCo² supports a network of mutually distrustful medical institutions that act as data providers (DPs) and hold subjects' records. An authorized researcher (see Figure 1) can run queries without threatening the data confidentiality and subjects' privacy. The DPs are considered semi-honest and the researcher is considered malicious. If required, our system can also use zero-knowledge proofs and an immutable distributed ledger to cope with malicious DPs.

Figure 1. System Model.

3. Proposed Solution

The two main building blocks in MedCo² are MedCo [8] and Drynx [9]. MedCo is an operational distributed system that enables authorized researchers to explore cohorts distributed across several institutions, by filtering subjects with inclusion/exclusion of clinical and genetic criteria. Drynx enables the computation of statistics, such as standard deviation or extrema, and the training and evaluation of machine-learning models on distributed data. In order to ensure data confidentiality and individuals' privacy, both systems rely on distributed interactive protocols, homomorphic encryption and differential privacy. In MedCo², we combine MedCo's capabilities to privately identify a set of sub-

jects matching precise criteria with Drynx's ability to perform computations on the identified subjects' records. As a result, we provide a fully-decentralized system that enables multiple functionalities and enforces privacy and security guarantees that are stronger than in any (to the best of our knowledge) existing solutions [10,11].

We now briefly describe the MedCo² data model, before explaining how a query is executed. DPs have two separate databases: (1) the local database, that is in cleartext and is only accessible from within the institution, and (2) a research database, open to external queries, in which data are encrypted. We define a micro-ETL (extract, transform, load) process that encrypts selected data from the local database and transfers them to the research database. In our system, the data stored in the research databases and all those involved in the query execution are homomorphically encrypted under the DPs' collective key, as described in [9]. A researcher creates a query containing the subjects' selection criteria along with the computation she wishes to perform on the selected subjects' records (step 1 in Figure 1). This query is broadcast to the DPs who privately retrieve the list of subjects satisfying the query and initiate a local data retrieval process (step 2). In this process, each DP stacks the received query and the retrieved subjects' identifiers inside its research database. This stack is periodically emptied by the local operating database that pulls the waiting queries and authorizes them (e.g., based on regulations, local policies). If the query is accepted, each DP performs some query-dependent pre-computation on its local database, before encoding and encrypting its contribution to the secure protocol (step 3). These contributions are then collectively aggregated under homomorphic encryption, to obtain the encrypted results (step 4). At this point, the results are obviously switched from the collective key to the researcher's private key (Collective Key Switching protocol), and sent back to her (step 5). MedCo² executes, in parallel to the query execution, a micro-ETL in which it encrypts the attributes involved in the query and stores them in the research database. This means that when a DP receives another query on the same attributes, it can directly answer from the research database, thus reducing its workload for upcoming queries.

4. Evaluation

We implement and showcase MedCo² within a representative scenario that involves clinical and genetic data sharing. We integrate it in MedCo by enhancing its data model and query language/interpreter to seamlessly enable an authorized researcher to execute operations on a cohort built from MedCo.

We present MedCo² performance for a worst-case scenario: a query that it has not seen before, i.e., we assume that all the computation happens *on the fly*, with no pre-computation. Figure 2 shows the timeline of a query execution in MedCo², comprising the steps of (a) query creation at the client, (b) query broadcast to the DPs, (c) collective query reencryption at the DPs (in order to enable matching queries [8]), (d) local DB execution and result retrieval at each DP, (e) local encoding of the matching patients' data at each DP, (f) collective aggregation of the target function across all DPs, (g) collective key switching of the results to the querier's key, and (h) decrypting and decoding at the querier. In this case, 18132 patients satisfy the filtering criteria and are retrieved among 150,000 patients distributively stored in 12 databases. As shown in [8,13], the overhead time for data discovery (including Step 1, which comprises Query Creation,

Figure 2. MedCo² Query Execution Timeline. *LC* =Local Computations, *CC* =Collective Computations.

Query Broadcast and Query Reencryption, and Step 2, composed of Database Execution and Result Retrieval) when executed on encrypted data is negligible, in this case 2 seconds, with respect to the same operation executed on cleartext data. Figure 2 also shows that MedCo² can perform a logistic regression on a distributed dataset with 100 features in less than 23 seconds. The distributively trained models achieve accuracy results similar to their centralized, non-secure counterparts, as shown in [9]. We observe that the whole MedCo² process is performed in less than 98 seconds if 18132 patients out of 150000 satisfy the selection criteria. The *DPs*' local query execution in MedCo (DB execution in Figure 2) is the most expensive operation, as it linearly depends on the number of selection criterias in the query and on the total number of observations in the database (each patient has thousands of observations).

Finally, MedCo² enables a researcher to train and evaluate linear and logistic regression models on a chosen cohort without accessing the actual subjects' records. This makes the task more cost-effective and streamlines a process that is at the core of many common medical workflows such as GWAS.

5. Conclusion

MedCo² addresses the privacy and security challenges of highly distributed medical-data sharing networks by avoiding single points of failure and by providing the following unparalleled functionalities and properties: (a) privacy-preserving cohort exploration and analysis over distributed databases held by distrustful *DPs*, (b) distributed training of simple machine learning models, (c) data confidentiality and individuals' privacy through collective keys and distributed protocols, and (d) a usable example scenario through its integration in a deployed system featuring a modern graphical user interface [8]. MedCo² aims at enabling the promises of personalized health by facilitating and streamlining the data discovery and analysis processes.

Mixed and Augmented Reality Tools in the Medical Anatomy Curriculum

Melanie ROMAND^{a,1}, Daniel DUGAS^b

Christophe GAUDET-BLAVIGNAC, BSC CS, MMED^a Jessica ROCHAT^a and
Christian LOVIS, MD, MPH, FACMI^a

^a*Division of Medical Information Sciences, University Hospitals of Geneva, Geneva, Switzerland*

^b*Autonomous Systems Lab, ETH, Zurich*

Abstract. The use of augmented reality (AR) in the medical field has grown since 2007-2013 and was first introduced in surgical departments. AR and mixed reality (MR) allow us to explore complex structures, observe phenomena that are difficult or impossible to see otherwise, and interact with the virtual structures they display. Recently, they are beginning to be adopted for education. This work examines whether new AR and MR technological tools, when used in the context of anatomical teaching, can allow for strengthening of teaching quality - for example by overcoming new or existing constraints such as the limited availability of dissection specimen. This work also considers how these technologies are to be applied efficiently and practically in teaching. An attempt is made to answer these questions in three stages: i) a non-systematic review of the literature ii) a review of augmented reality solutions for anatomy available on four different platforms iii) a 30-person study of the usability of augmented reality. The results show that there is potential for AR and MR to supplement anatomical teaching, but that traditional methods remain indispensable.

Keywords. augmented reality, mixed reality, anatomical teaching, e-learning, digital tools for supplementing medical teaching

1. Introduction

Anatomy is a fundamental branch of the medical curriculum. As the human body is the target of daily interventions and investigations, this discipline is a cornerstone of physicians' medical skills. Anatomical knowledge allows for safe and quality medical practice, through the understanding of decisions and actions taken and the fact that it contributes to effective communication between health professionals [1]. Given its importance, its teaching should be as effective as possible, in terms of accuracy of the acquired knowledge, and its resilience.

Since the Renaissance, the study of corpses and their dissection have been the main means of teaching anatomy [2]. Today, this discipline is traditionally taught in the pre-clinical years and provides basic knowledge in the four fields of macroscopic anatomy

¹Corresponding Author: Melanie Romand, Université de Genève, 24 rue du Général-Dufour 1211 Genève, Switzerland; E-mail: Melanie.Romand@etu.unige.ch

(including dissection), neuroanatomy, histology and embryology. Course material generally includes slideshows with verbal explanations, bodies for dissection, presentations of already dissected body parts and books with two-dimensional images [3].

Since its inception, the field of anatomical teaching faces several practical constraints. These include the time allocated within the medical curriculum, the practicality of using human bodies and the ethical and emotional dimension surrounding the handling of corpses by students. Some of those constraints are relatively new, or are currently increasing in severity. The evolution of the constraints which apply to the field of anatomical teaching, raises the question of whether the tried and true methods are still optimal. In addition, technological advances make previously unavailable medias and modalities possible. This raises the questions of how modern technologies could be used to supplement the teaching of this discipline, whether applying these tools would lead to improved efficiency in practice, and what additional challenges technologically augmented anatomical teaching might present. Previous work [3] shows that anatomy learning is most effective when the desired structures can be examined from all angles and at any time. Recent technological advances in the field of virtual, mixed and augmented reality have led to the emergence of widely available consumer software, academic or commercial, which focus on anatomy learning.

One aspect of this work consisted in evaluating the already-available tools and solutions in the academic and commercial field, through a literature review and application inventory. In a second stage, two of the most promising mixed-reality applications were selected in order to conduct a usability study, with the participation of medical students. This usability study focused on the hands-on evaluation of two applications available on Microsoft's mixed reality headset, "Hololens". The results collected throughout this study are evaluated in order to extract recommendations in proposing an evolution in the teaching of this discipline.

2. Methodology

2.1. *Nonsystematic Literature Review*

A literature search was conducted on the following search engines and knowledge bases: PubMed, Google scholar, Embase/Elsevier/ScienceDirect, Wiley Online Library, Web of science, and more. The inclusion criteria for literature was: The article must discuss the topic of AR/MR in the general field of medicine OR the article must discuss the topic of AR/MR in the teaching of anatomy.

2.2. *Study of Available Solutions*

Presently, the most widely used AR devices are consumer smartphones and tablets [4]. In the pursuit of studying available AR and MR solutions, the three most promising AR and MR platforms were identified, and software available on those platforms was tested and evaluated. Selection criteria: Software was selected for evaluation according to the following criteria: i) the software must focus on human anatomy ii) the software must present significant AR or MR capabilities. iii) the software must be available for use on the Hololens, Apple device, or Google Play device platforms. Of the selected software, a

sub-selection was made based on available user-review ratings. Finally, a small portion of the selected software was excluded due to practical limitations. Each remaining software solution was tested in-person, and evaluated according to a consistent evaluation scheme. The evaluation scheme was formed to include as much potentially relevant information as possible for anatomical teaching providers.

2.3. Usability Study

The usability study conducted in the course of this work can be modeled in three parts. The experiment set-up: the target demographic for the study was medical students, in the 2nd to 5th year. 1st and 6th year students were not targeted due to a lack of complete ongoing anatomical curriculum. 30 medical students signed-up for and participated in the study. The hands-on experiment: two solutions were selected based on their ease-of-use, relevance and completeness: "Dynamic Anatomy" and "Holoanatomy", both MR applications intended for and tested on the HoloLens. Hands-on experimentation: during 30 minutes, participants were to interact with both selected MR solutions, in a semi-supervised manner. Structure was given, but not imposed in the participants' interaction with each application. Assistance was available and given on request. Then a usability questionnaire, developed based on the standard set by [5], was filled in by participants after they had completed all other tasks. The questionnaire contained 4 sections: 1) **statements** concerning their experience with MR, 2) perceived **positive and negative** aspects, 3) a **multiple-choice** question regarding their preferred mode of anatomy teaching, and 4) **arguments** supporting their choice on the multiple-choice question.

3. Results

3.1. Nonsystematic Literature Review

Using the criteria outlined in Subsection 2.1, 27 existing articles were selected for review. 8 of the reviewed articles relate to describing evolution in the topic of AR in anatomical teaching. 19 of the reviewed articles concern tools presently available to apply AR and MR technologies.

Work by [6] describes the evolution of AR use in medical scenarios, and identifies a rise in activity for these topics in the years 2007-2013. The terms MR and AR are used inconsistently in the literature. As a result, tracing back the evolution for MR specifically is challenging. Technical limitations have contributed to hindering the introduction of AR to the medical field [7] Despite this, research projects involving the use of AR in medical scenarios, and specifically in anatomical teaching were identified. Previous works look at the use of AR in surgery [6], neurosurgery [8], and oto-rhino-laryngology [9] Research towards the use of AR for anatomical teaching dates back at least as far as 1997 [10]. Since then, several works [11] have focused on applying AR in medical teaching.

3.2. Available AR and MR Solutions

52 applications were selected, 26 of those available on the Apple ecosystem, 16 on the Google Play ecosystem, and 10 on the HoloLens. Of those, 35 applications (respectively 17, 8, and 10 for Apple, Google Play, and HoloLens) could be tested in person.

Table 1.: Open-ended 3-positive-3-negative-aspects questionnaire results

Hololens for anatomy teaching				MR for anatomy teaching			
Positive	%	Negative	%	Positive	%	Negative	%
Ease of use	26%	Discomfort	35%	3D Visualization	22%	Discomfort	30%
Adjustability	10%	Field of view	22%	Practicality	18%	Missing touch	17%
Convenience	9%	Price	19%	Super-real		Space required	17%
Comfort	9%	Software bugs	10%	visualization	15%	Little benefit	
Low weight	9%	Availability	7%	Stimulating	12%	compared to PC	10%
Interactivity	9%	Non-trivial		Interactivity	10%	Lack of realism	8%
Portability	7%	learning curve	7%	Increased		No social aspect	8%
Intuitiveness	7%			understanding	9%	Lack of real body	5%
Image quality	7%			Innovative	8%	Non-mature tech.	5%
Voice, gesture				Add, remove, and			
recognition	7%			isolate structures	6%		

The overall resulting impression is as follows: At the time of this study, MR/AR applications exist which could be used as tools to supplement anatomy teaching. However commercial solutions do not yet exist for every body part, or are not suited for all specific teaching modalities. A knowledge base of these evaluations was compiled and is made freely available (www.dugas.ch/public/realite-mixte-app-evaluation-data). Based on these evaluations, the Hololens platform was selected for the usability study described in Subsection 2.3.

3.3. Usability Study

The usability questionnaire contained 4 sections. The results obtained for each section are as follows:

The **statements** supplied in the questionnaire were graded on a scale from 1 (worse) to 7 (best). The mean score by category was 5.03 for the usefulness, 5.42 for ease of use, 6.2 for ease of learning and 5.63 for satisfaction. The overall grade was 5.47. Full results are available on request.

Responses to the open-ended **3-positive-3-negative-aspects** questionnaire were grouped into conceptual categories, semantics aside. Those categories, and the frequency at which participant responses fell into the relevant category are shown in Table 1.

As shown in Table 2, in the concluding **multiple-choice** poll, following hands-on testing of MR tools and existing software, an overwhelming majority of students expressed a desire for both classical methods and technological tools to be used in the teaching of anatomy in the medical curriculum.

In the open-ended supporting **arguments** question, participants were asked to motivate their choice. Responses to this open-ended question were grouped based on conceptual similarity. Arguments for using MR in anatomical teaching fell into the following categories: i) Access to specimens, and in particular the ability for home-work, which is difficult with real specimens. ii) Access to otherwise-impossible (referred to as *super-real* in this work) visualizations, such as dynamical properties, hidden structures, etc. Arguments for traditional methods fell into the following categories: i) realism, and the ability to show details which digital media can not practically capture ii) the psychological impact of real bodies on professional maturity iii) the importance of all senses in anatomy learning.

Table 2.: Preferred modality to be used in anatomical courses

Proposed general statement	selected %
Only MR methods, with Hololens	3%
Only currently used, traditional methods	11%
A combination of traditional and MR methods	86%

4. Conclusion

It has been shown that practical factors such as a high number of students, passive participation, difficult concepts [12], and a large quantity of material to be learned, can lead to sub-optimal or superficial learning for students in medical anatomy. Proper spacing of study sessions is important for optimal long-term memorization [13]. Use of AR and MR anatomical teaching could pose several advantages, such as the possibility of increasing the frequency of learning instances, interaction with models and specimens which are rare in practice, and super-real visualizations. This work shows that medical students are open to the introduction of technological tools to supplement, though not replace, traditional anatomy teaching. Potential future work involves extending the scope of the present study, and conducting a feasibility study from the perspective of anatomy teachers.

Modulation of Medical Condition Likelihood by Patient History Similarity

Jonathan TURNER^{a,1}, Dymphna O’SULLIVAN^b and Jon BIRD^c

^a City, University of London, London, UK

^b Technological University Dublin, Dublin, Ireland

^c University of Bristol, Bristol, UK

Abstract. Introduction: We describe an analysis that modulates the simple population prevalence derived likelihood of a particular condition occurring in an individual by matching the individual with other individuals with similar clinical histories and determining the prevalence of the condition within the matched group. **Methods:** We have taken clinical event codes and dates from anonymised longitudinal primary care records for 25,979 patients with 749,053 recorded clinical events. Using a nearest neighbour approach, for each patient, the likelihood of a condition occurring was adjusted from the population prevalence to the prevalence of the condition within those patients with the closest matching clinical history. **Results:** For conditions investigated, the nearest method performed well in comparison with standard logistic regression. **Conclusions:** Results indicate that it may be possible to use histories to identify ‘similar’ patients and thus to modulate future likelihoods of a condition occurring.

Keywords. EHR; machine learning; clinical terminologies

1. Introduction

The advent of electronic information systems in recent decades has enabled a rapid increase in data creation and collection in many disciplines, not least in healthcare, where we now have large amounts of data stored in individuals’ electronic health records. These data have been acquired during the care of individuals with a variety of aims: to improve the care of the individuals; to improve communications between individuals’ care givers; to maintain records of care; and to enable appropriate charging to payers [1]. Electronic records generally now hold data dating back 30 years or more and exist in various healthcare enterprises and departments for a variety of purposes – e.g. booking systems, GP systems, lab test results, imaging – and contain a number of data items, such as demographic information, test results, diagnoses, treatments, clinic appointments and charging information. In the work presented here, a set of longitudinal primary care records was analyzed to see if patients with similar recorded histories of symptoms and diagnoses were likely to share similar future diagnoses. The analysis of Electronic Health Records (EHR) data for risk prediction is an active area of research [2] however scant work using solely primary care records data for general future conditions likelihood was found. Miotto et al [3] used secondary care EHR data to make such predictions for a number of conditions using deep learning, achieving an

¹ Corresponding author: Jonathan Turner, Centre for Health Informatics, City, University of London, Northampton Square, London EC1V 0HB, United Kingdom; E-mail: jonathan.turner@city.ac.uk.

F-score of 0.236 for their predictions. Weng et al [4] tested four machine learning algorithms (random forest, logistic regression, gradient boosting machines, neural networks) to predict cardiovascular risk. McCormick et al [5] describe a Bayesian hierarchical model for the selection of association rules, predicting future medical histories for individuals on the basis of common clinical histories. Wang et al [6] developed a multilinear sparse logistic regression for risk prediction with patient EHRs for joint risk prediction (two or more diseases that are related to each other in terms of sharing common comorbidities, symptoms, risk factors). In summary, other work to date has primarily been on secondary care records for patients being treated in hospital settings as part of single episodes; the work we describe here investigates the use of primary care records that record events over many years.

2. Objective

With many symptoms being common to multiple diseases, there is a challenge in producing an initial diagnosis or recommendation for diagnostic tests from a set of symptoms that could have been produced by a number of diseases. Often the initial choice of diagnosis or testing is based on a clinician's impression of the likelihood of that condition in a general population; however the opportunity may exist for modification of these likelihoods based on individuals' recorded histories. In this work we aim to investigate the potential of applying machine learning methods to medical histories, in order to see if we can predict whether an individual's chances of being diagnosed with a particular condition are modulated from general population prevalence by comparison of their previous diagnosis and symptom histories with others' diagnosis and symptom histories. Jenssen and Kenyon note that 'medical decision-making is about assessing risk and weighing competing probabilities in the setting of imperfect information' [7]. We used coded histories from primary care records as the basis for this work. Primary care records, in general, utilize coding systems to store diagnosis and other information about patients. Common coding systems used for these records include ICD9, the dominant system in primary care in the USA and now being replaced by ICD10; and the Read Code system, the dominant system in the UK but now being replaced by SNOMED CT. Data used in this study were derived from UK patients, coded using Version 3 of the Read Codes (CTV3), and US patients, coded using ICD9. We chose CTV3 as the primary coding system. Some data required translation from ICD9 to CTV3 using a look-up table created from existing look-up tables for ICD9 to SNOMED CT from NIH [8] and for SNOMED CT to Read CTV3 from NHS Technology Reference Data Update Distribution Service [9]. Each CTV3 term is associated with a single concept and consists of a 5 byte code with an optional 2 byte. Codes comprise letters, numbers and trailing decimal points and fall into one of three categories: findings and diagnoses; processes; and medications. All codes are arranged in a hierarchy with a table listing all parent-child relations.

Figure 1 shows a small extract from the

Figure 1. An example of codes in the CTV3 hierarchy.

CTV3 hierarchy, illustrating the relationship between codes relating to bacterial chest infections. This Figure shows that Acute haemophilus influenza bronchitis is a Haemophilus influenzae infection; there are four other codes that are child codes of Haemophilus influenzae infection. Haemophilus influenzae infection itself is a Haemophilus infection, which in turn is a Bacterial disease. Bacterial disease is an Infective disorder, a child code of Clinical findings, a category coming under the root node of the CTV3 tree.

3. Methods

The data sources were sets of longitudinal clinical records derived from general practice data across the UK and USA, de-identified prior to being made available to us for this work. Data were presented as a set of records of events, including patient age, gender, and codes of events including diagnoses, symptoms, administrative events and prescriptions, together with the year of the event and history of smoking and alcohol consumption. There were 25,979 patients in the full data set (49.3%M, 50.7%F), with a total of 749,053 recorded items, of which 375,312 items were diagnostic events. Age distribution and prevalence of common conditions (as determined by [10]) in the full data set was not different to that present in the general population. For this work, only diagnosis and symptom codes and those codes giving information about smoking and alcohol consumption were retained from the records in the data set. The Konstanz Information Miner (KNIME) [11] was used to prepare the data and merge the data sets; statistical analysis was performed using R [12]. All software was run on an Asus N56VM laptop with Intel Core i7-3610QM 2.30 GHz CPU with 8GB RAM running 64-bit Windows 10.

For each record, the codes retained were used to determine its k nearest neighbour (KNN) records by use of the binomial method [13] using a program written in R for this work. Optimum values for k , the number of nearest neighbours, were established for each condition by experimentation on a training set of records removed from the complete data set, where the F-measure of accuracy was optimized over a range of values for k . The most effective depth in the CTV3 tree at which to aggregate codes from deeper levels was similarly determined by experiment. Calculations were repeated for a set of medical conditions. The process was run separately for each condition, with the condition of interest hidden from the information used for the distance calculation. For each record, the prevalence of the condition in the KNN was compared to the prevalence in the remainder of the data set; those records where the prevalence in the neighbours was significantly ($p < 0.05$) higher than in the remaining records, were assigned a prediction of positive for the condition of interest, otherwise the prediction was negative. Predictions were then compared to the actual presence in each record.

4. Results

An example is given for a single condition, allergic rhinitis. A Fagan nomogram [14] of the changed probability of an individual having the condition is illustrated in Figure 2. The prior probability of an individual having the condition, i.e. the population prevalence, is 0.178. After implementing the nearest neighbours algorithm, (the 'test') those predicted to have the condition had a probability of having the condition of 0.252.

The sensitivity of the test was 0.599; the specificity was 0.614. Results for six conditions are shown in Table 1. The results include comparison with a simple logistic regression (LR) method, chosen as an established prediction method [2].

KNN generally performed better than LR when judged by F-score, sensitivity and specificity, for all conditions. Low prevalence conditions performed poorly with LR, predicting no positive cases. Because of LR’s better performance in positive likelihood ratio, it also gave higher results for odds ratio than KNN, suggesting that if LR predicts positive for a condition then there is greater confidence in the record containing that condition than if KNN predicts positive. However, if LR predicts negative for a record then there is less confidence that the record does truly not contain the condition than if the KNN predicted negative. F1 scores achieved for the more common conditions compared well with those achieved by Miotto et al [3]. Additionally, the KNN method presents an explainable method that may be more convincing than other machine learning methods in a clinical setting [4].

Figure 2. Results for allergic rhinitis using k-nearest neighbours.

Table 1. Comparison of KNN and LR prediction methods for six conditions.

Condition	Number in data set	Method	F1 Score	F2 Score	Sensitivity	Specificity	Positive Likelihood Ratio	Negative Likelihood Ratio	Odds Ratio
Allergic Rhinitis	2297	KNN	0.354	0.469	0.599	0.614	1.550	0.654	2.37

		LR	0.137	0.095	0.079	0.996	21.649	0.925	23.413

5. Conclusions and Future Work

The results of our analysis indicate that it is possible to apply nearest neighbour techniques using medical histories to modulate future likelihoods of a condition occurring in individual patients. The technique employed in this work showed

performance improvements over logistic regression methods particularly for conditions of low prevalence, although there were limitations due to the relatively small data set size. This method is suggested as a useful low-cost screening tool. Early discovery of a condition can often improve the chances of successful treatment or of mitigation of the effects of the condition and many conditions can be detected through screening tests on asymptomatic individuals. Disadvantages of conventional screening tests include risks of harm to the individual if the screening test is invasive; inconvenience and/or stress to the individual; and financial cost to the individual and/or the health care system. It is therefore advantageous to perform screening tests on subsets of the population selected to be at great risk of the condition being screened for [15].

We intend to extend our analysis in a number in a number of areas. We will repeat the analysis using the existing methods but translating event codes to SNOMED CT and comparing results to those described here. We intend to optimize the methods used to address the slow run time experienced in this analysis. Run time has implications for use in clinical practice: currently the system takes around 30 minutes to run on a sample of 5,000 records. This is likely to be too long for opportunistic likelihood predictions for an individual arriving in a clinic, although acceptable for use in identification of individuals appropriate for screening or invitation to consultation.

MQT-Tz: Secure MQTT Broker for Biomedical Signal Processing on the Edge

Carlos SEGARRA ^{a,b,1}, Ricard DELGADO-GONZALO ^a and Valerio SCHIAVONI ^b

^a CSEM, Neuchâtel, Switzerland

^b Université de Neuchâtel, Neuchâtel, Switzerland

Abstract. Physical health records belong to healthcare providers, but the information contained within belongs to each patient. In an increasing manner, more health-related data is being acquired by wearables and other IoT devices following the ever-increasing trend of the *Quantified Self*. Even though data protection regulations (e.g., GDPR) encourage the usage of privacy-preserving processing techniques, most of the current IoT infrastructure was not originally conceived for such purposes. One of the most used communication protocols, MQTT, is a lightweight publish-subscribe protocol commonly used in the Edge and IoT applications. In MQTT, the broker must process data on clear text, hence exposing a large attack surface for a malicious agent to steal/tamper with this health-related data. In this paper, we introduce MQT-Tz, a secure MQTT broker leveraging Arm TRUSTZONE, a popular Trusted Execution Environment (TEE). We define a mutual TLS-based handshake and a two-layer encryption for end-to-end security using the TEE as a trusted proxy. We provide quantitative evaluation of our open-source PoC on streaming ECGs in real time and highlight the trade-offs.

Keywords. wearables, mHealth, secure broker, MQTT, mosquito, TrustZone

1. Introduction

Personalized health and medicine has the potential of being the next revolution in healthcare. It is also referred as the P4 medicine (Predictive, Preventive, Personalized, and Participatory), and provides the opportunity to benefit from more targeted and effective diagnoses and treatments [1]. One of the driving forces behind this tendency is the increasing medicalization of wearable technology [2] and mobile health (mHealth) apps [3]. In order to enable these technologies, complex processing IoT pipelines are gradually being deployed or repurposed. When the data-in-motion are vital signs, protecting user's privacy becomes a topic of crucial importance. Recent data protection regulations (e.g., GDPR [4]) stress the importance of protecting sensitive information against malicious attackers or untrusted cloud providers.

Message Queuing Telemetry Transport (MQTT) [5] is one of the most commonly-used communication protocols in IoT. In spite of that, it is not included in some of the most extended Medical-Grade data exchange standards [6,7]. It follows a publish-subscribe architecture specially designed for environments with limited memory and reduced network bandwidth. In such circumstances, MQTT has proven to be more adapted to the IoT than classical protocols such as HTTP [8]. In MQTT, a *client* publishes data to a *topic*

¹ Corresponding Author: Carlos Segarra; E-mail: carlossegarragonzalez@gmail.com.

and the *broker* forwards it to each client that previously subscribed to it. The protocol is currently used in a variety of settings: data generation by sensors, pre-processing on the edge, and forwarding to the cloud. Examples include live heart-rate data [9,10], smart-grids [11], or building management systems [12]. Most MQTT implementations support TLS for transport security in the client-broker link, preventing malicious actors from spoofing application data. However, the broker itself still exposes a great attack surface [13].

In order to protect the privacy of health-related data, we present MQT-TZ, a secure implementation of the MQTT broker leveraging Arm TRUSTZONE, a Trusted Execution Environments (TEE), widely available on edge devices [14]. TRUSTZONE is a security feature available in recent Arm processors that enables system-wide hardware isolation for trusted software [15]. Our prototype builds atop *mosquitto* (<https://mosquitto.org>), a popular MQTT broker implementation, and includes persistent storage of client's keys in Arm's tamper-proof secure storage, as well as TEE-protected re-encryption of application data. These security enhancements make our ecosystem compliant with the "Services Secure Interface" [6] described by the Personal Connected Health Alliance, and address several attack vectors listed [7] by the IHE. We also consider linking our secure broker to a larger storage utility where data-at-rest is encrypted and its origin authenticated by MQT-TZ.

The paper is organized as follows. In Section 2, we describe the technical architecture and implementation of MQT-TZ. Then, in Section 3, we evaluate its performance and robustness at processing 1-lead ECGs in real time. Finally, in Section 4 we expose our main conclusions and propose further lines of research.

2. MQT-TZ: Securing the MQTT Broker

2.1 Architecture & Component Description

TRUSTZONE splits the system in a hardware-protected trusted part (the TEE) and an untrusted one (also called Rich Execution Environment, or REE). We add an encryption layer in MQTT's payload using client-specific keys stored in Arm's secure storage. This way, application data is only processed in clear inside the TEE. For the additional key-provisioning, we redefine the client authentication in the mutual TLS handshake to prevent the REE from gaining access to clients' keys.

The overall workflow looks as follows. Data travels two-fold encrypted from the client to the broker (Fig. 1: part 1). Once the client access is confirmed, Fig. 1: part 2, the subscribers for the given topic are retrieved and the payload forwarded (Fig. 1: part 3). Then, encrypted data is transferred to the TEE (Fig. 1: part 4). The origin and destination client keys are retrieved (fig. 1: part 5-7), the payload is re-encrypted, and sent back to the REE (Fig. 1: part 8) and to the subscriber (Fig. 1: part 9).

Two-Step Handshake. MQT-TZ defines and uses a two-step handshake that realizes broker and client authentication with end-to-end encryption from the client to the TEE. The handshake protocol requires minimal pre-provisioned cryptographic material. The broker (server in TLS nomenclature) authentication is done through TLS' handshake, supported by default in *mosquitto*. The client authentication is done through MQTT. It publishes its symmetric key, encrypted with the broker's TEE public key, to a specific

write-only topic. This TEE key-pair is generated at device start-up time (secure boot) and derived from a Hardware Unique Key (HUK).

Layered Encryption & Access Control Mechanisms. Once the initial handshake is finished, MQT-TZ uses a two-layer encryption mechanism. First, the client-broker link is protected by TLS within MQTT. Second, MQTT's payload field is encrypted using the clients' symmetric key. Then, data is re-encrypted in the TEE (explained next) and sent to destination over MQTT-TLS. Doing so, we achieve end-to-end security relying on TRUSTZONE as a secure proxy.

Payload Re-encryption. The core secure functionality implemented in MQT-TZ is the payload re-encryption. We link MQTT with a Trusted Application (TA) running inside the TEE that transfers the encrypted data to the Secure World, retrieves the origin and destination keys from secure storage, and re-encrypts the information. Currently, topic subscription lists and MQTT metadata are stored in a dedicated database (MQTT DB) in the REE. We plan on shadowing these structures and keeping them in the TEE.

Lightweight Cache. MQT-TZ embeds a lightweight cache that keeps the most re-cent keys in the TA's heap memory, and evicts the least used to persistent secure storage.

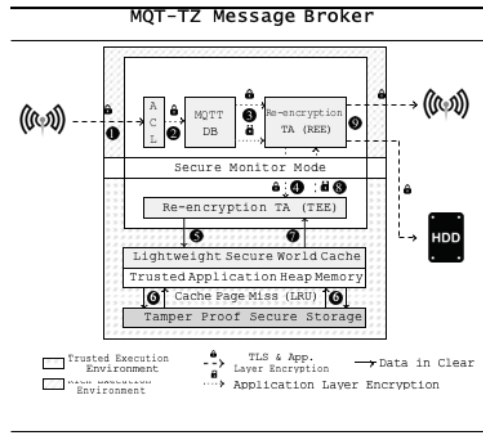

2.2 Implementation Details

MQT-TZ is implemented in C. The current version of MQT-TZ adds 400 SLOC to mosquitto and the TA amounts to 1184 SLOC. The MQT-TZ TA relies on OP-TEE (<https://www.optee.org>), an open-source framework with native support for TRUSTZONE. Our implementation will be publicly available (<https://github.com/mqtttz>).

Client and Server Authentication. The server-side authentication is done through vanilla TLS. We deploy MQT-TZ's secure broker in a device with a static IP address. Then, we bound the address to a domain name and use a certificate. We rely on *Let's Encrypt* (<https://letsencrypt.org/>) to get one and to authenticate the broker. The client-side authentication uses MQTT as communication layer, and openssl (v1.1.1a) for cryptographic primitives and operations. The integration with mosquitto exploits custom callbacks for each packet processing. In addition, we use MQTT Re-quest/Response (RR) features (since v5) for the client's key exchange. To control access and R/W permissions to topics, we use mosquitto's ACLs.

Trusted Application. We use OP-TEE to implement the payload re-encryption TA. Code developed within this framework has two parts: (1), a host app that runs in the REE and acts as entry point and bridge to the TEE, and (2) a trusted API in the TEE that exposes different functions. MQT-TZ intercepts all MQTT packets being forwarded to the recipients, and feeds our host app with both client's IDs, and the encrypted data. We then perform the

Figure 1. MQT-TZ Architecture and data flow.

payload re-encryption using OP-TEE's storage and cryptographic libraries. TRUSTZONE not only provides isolation between worlds, but also between different TAs. Hence, we use the same secure API to store new keys during the handshake. For the key retrieval, we plan to implement a small LRU cache to store the most frequently used keys in the TA's heap, and the rest in persistent secure storage.

3. Evaluation & Discussion

In this section, we perform an evaluation of MQT-TZ. First, we benchmark the TA re-encryption with random data in order to understand the overhead introduced by the re-encryption; and then, we analyze the CPU and network throughput when monitoring vital signs in a real setting. For all experiments, we virtualize a Raspberry Pi 3 using QEMU-V8 (<https://www.qemu.org/>) running mosquitto v1.6.3 and OP-TEE v3.5.0.

3.1 TA Re-encryption

In Fig. 2, we show the breakdown of the time required to re-encrypt a single block of data for different sizes. The time is split in the time to retrieve each key (retrieve dec key, retrieve enc key), encrypt, and decrypt. We can observe that AES is two orders of magnitude slower in the TEE. This is a consequence of OP-TEE not using hardware accelerators in contrast to openssl in the REE. Moreover, we observe sensible slowdowns when switching from in-memory to secure persistent storage.

Figure 2. Re-encryption TA microbenchmark

3.2 Realtime ECG processing

In this case, we test the resilience of MQT-TZ at sustaining the workloads that can be encountered in a hospital. For the experiments, we use the LTMS-S [16] platform developed by CSEM for the European Space Agency (ESA). In particular, we simulate 50 patients streaming in real-time 1-lead electrocardiograms (ECGs) at a frequency of 321.25 Hz. All ECGs are streamed toward a single MQT-TZ broker. In Fig. 3, we depict the outbound throughput generated by each publisher measured using nethogs (<https://github.com/raboof/nethogs>). We observe that at any given time only a subset of the publishers actually emits data. A single subscriber streams at 350 Bytes/s in the worst case, and the full collective generates between 3 to 5 kBytes per second. During the experiment, we recorded using

Figure 3. Workload test: Network throughput (top) and CPU usage (bottom)

dstat (<https://github.com/dagwieers/dstat>) the CPU load at the broker, shown in Fig. 3. We observe that after the initial peak, the overall CPU usage (both for usr and sys processes) stabilizes at 60%.

4. Conclusion and Future Work

Motivated by the lack of secure-by-design communication protocols for the Edge, we presented MQT-secure implementation of the MQTT broker using TRUST-ZONE and showed its direct application in a in-hospital setting. The proposed system is robust and capable of managing 50 patients in real-time with a CPU usage of 60%. We plan to extend this work along the following directions. First, we will compare MQT-TZ against other publish-subscribe protocols and messaging queues. Second, we will study the performance overhead of MQT-TZ when deployed on large-scale scenarios. Finally, we intend to look into the energy footprint, an aspect of paramount relevance for edge deployments.

Abstract. Extraction and use of Electronic Health Record (EHR) data is common in retrospective observational studies. However, electronic extraction and use of EHR data is rare during longitudinal prospective studies. One of the reasons is the amount of processing needed to assess data quality and assure consistency in meaning and format across multiple investigational sites. We report a case study of and lessons learned from acquisition and processing of EHR data in an ongoing basis during a clinical study.

Keywords. Data integration, clinical trials, data quality, data processing

1. Introduction

Large sets of electronic health record (EHR) data present an exciting possibility for research such as epidemiologic and observational research, real-time data collection, safety surveillance and regulatory uses and prospective clinical research. [3,4,6] Although this data has much potential, there are many issues that must be addressed in order to produce consistent and reliable findings. [10] EHR data are data collected in the process of care. Since the primary purpose of EHRs is to support activities such as clinical workflow and billing, the resulting data format, structure and quality often differ from the carefully scheduled, collected and formatted data required for research. In addition, EHR data changes over time reflecting (1) changes in the health status of the patient, and (2) changes in technology, data representation formats, regulatory incentives and institutional factors. [5] These variations in expected data versus collected data (e.g., timeliness, accuracy) are collectively referred to as data quality

dimensions. [8,11]

EHR data provide useful information about a patient and their healthcare only if the data quality is high and correspond to the real world. This correspondence varies widely, as do the measurement methods employed in the published literature. [1; 9] Further, the reasons for observed inconsistencies are rarely reported. To address this deficit in our understanding of data quality in healthcare data, the Patient Centered Outcomes Research Institute (PCORI) EHR Data Quality Study compares EHR and patient self-reported data for 34 conditions, 8 medical procedures, hospitalizations, and smoking status in cohorts from two southern U.S. states (Arkansas and North Carolina). This report outlines the data acquisition and processing of EHR data for this study. Briefly, the study required near real time acquisition and processing of EHR data to facilitate the comparison of EHR with self-report data to (1) identify discrepancies between these sources, and (2) support subsequent EHR data investigations and patient interviews on a weekly basis.

2. Methods

We report on the common aspects of data acquisition and processing between the two regions. Inpatient data from large hospitals were extracted from institutional data warehouses. Data from outpatient clinics were obtained either directly from the clinic EHR (North Carolina) or from an institutional data warehouse (Arkansas). Patient self-report data were compared with phenotypes derived from EHR data for the conditions, procedures, hospitalizations and smoking status from Arkansas and conditions from North Carolina.

For each phenotype, computational algorithms were developed to render a “self-report” answer and an “EHR answer”. Each was classified as “yes/confirmatory”, “don’t know/possible”, or “no/no evidence” in the self-report and EHR data respectively. Mismatches between EHR and self-reported phenotypes were considered a discrepancy. A subset of study participants were interviewed about their discrepancies. In the Arkansas cohort, participants were prospectively enrolled and the study required acquisition and processing of data on a weekly basis. In North Carolina, participants from a longitudinal community registry and biorepository, the Measurement to Understand Reclassification of Disease of Cabarrus/Kannapolis (MURDOCK) Study, have provided self-report data with annual updates as well as consent to access their EHR data. [2]

3. Results

For the North Carolina cohort, self-report data were managed in a custom-developed system. Existing self-report data were compared to newly acquired EHR data and discrepancy reports. For the Arkansas cohort, participants were prospectively enrolled at six clinics throughout the state. In Arkansas, self-report data were collected only once for the purpose of the PCORI EHR Data Quality Study. Data for the Arkansas cohort were managed in the open-source Community Edition of the OpenClinica Electronic Data Capture (OC-EDC) system. Discrepancies for both cohorts were double coded for root cause and correct data source in the OC-EDC system. The orchestration of these sources was accomplished with carefully timed data transfers and

SQL queries running over the entirety of the combined patient populations with 1,061,999 patients and 23,839,223 encounters.

Research Staff had real time access to EHR Data. For the Arkansas cohort, participant healthcare data were captured in either the Epic® EHR or various versions of Centricity®. These data were directly accessed through the EHR user interface by the research assistants (RAs) at enrollment to obtain participant medical record numbers (MRN) to for patient matching between self-report and EHR data. The RAs also used Epic to look up diagnostic information (1) prior to the telephone discrepancy interview when a discrepancy appeared likely due to clinical charting under the wrong patient or record linkage errors; and (2) for post interview attempts to confirm root cause. Because the study was operationalized differently in North Carolina due to previously existing EHR and self-report data, and because the clinics were separate institutions from the MURDOCK Study, EHRs in North Carolina were not accessed through the EHR user interface.

Acquisition of EHR data required substantial preprocessing. For the Arkansas cohort, all data were extracted from the institutional data warehouse for enrolled participants. The extracted data were stored in Microsoft SQL server and required several layers of conversion processing in order to integrate the regional program data with the hospital data. For the North Carolina cohort, EHR data were obtained from five local healthcare facilities with the following EHRs: Athena Health®, Allscripts®, Practice Fusion® and Epic®. The data from the different facilities were standardized and transformed to a common data model by the MURDOCK Study team. These data were linked with the self-report data, de-identified and sent to the study coordinating center for further processing. Record linkage between the incoming self-report data and EHR data was a deterministic match for both cohorts using the MURDOCK Study Number (North Carolina) and the MRN (Arkansas). Any linkage errors discovered in the EHR were collected as part of the study.

Following record linkage, each participant's EHR data were phenotyped. Phenotypes are rule-based definitions used for classification. Combinations of standardized controlled coded terminologies for healthcare (the International Classification of Diseases (ICD) and Current Procedural Terminology (CPT)), along with a few other non-coded data points identified from the existing literature and from practicing physicians, were used to develop the rule- based definitions. These were run over the entire dataset.

The phenotyping process was completed using stored procedures and each processing step was logged in case of failure. Overall, 140 phenotypes (70 "confirmatory" and 70 "possible") were specified and programmed. A total of 7,405 unique ICD-9 and ICD-10 codes were used in the process. Due to the long list of codes, a flexible design was necessary. Value sets for all phenotype definitions were kept in one table to be read by stored procedures, providing a quick and easy way to address unexpected phenotype results with simple table insertions/deletions as opposed to time consuming and risky code alterations. Records returned from the EHR for each phenotype run were compared with those from the self-report dataset. Each condition, procedure and event of interest for each participant was classified as "discrepant", "possibly discrepant" or "not discrepant". Discrepancies were then output to reports for RAs to use in the interview process. In addition to the discrepancy details, supplemental information such as ICD code descriptions were included to help characterize each discrepancy. Discrepancies were also imported into the OpenClinica system for post- interview coding (root cause and most likely correct data source) and

adjudication. Finally, coded and adjudicated discrepancies were exported from the OpenClinica system back to the Microsoft SQL Server for final post-interview discrepancy reports which were made available to participants.

To date, 2,151 participants have been enrolled in Arkansas. Of those, 1,096 participants have been successfully processed through discrepancy identification. Of the North Carolina cohort, 3,927 MURDOCK Study participants had EHR data and have been processed through discrepancy identification, of which 373 participants have been interviewed. The study is ongoing at this time.

4. Discussion

The lack of information about the level of correspondence between healthcare data and the real world is an impediment to various types of research. Data quality must not be an unknown. The PCORI EHR Data Quality Study is an effort to test dimensions of healthcare data quality over multiple phenotypes simultaneously in order to reveal data quality issues at scale and establish general measures and methods for characterization of data quality problems in health record data.

Modifications were needed in response to both internal and external changes. Some phenotypes were especially challenging, such as obesity, kidney disease and chronic obstructive pulmonary disease (COPD). Initially phenotypes were developed with broad definitions and code sets. Through iterations of ICD code tuning they were refined to more conservative sets that reflected the intent of the phenotype. In addition, an inherent dependency on data source systems provided challenges. Changes to institutional software along with a national migration from ICD version 9 to version 10 affected our design and led to reanalysis, redefinition and reprogramming. During system development, a new EHR system for the Arkansas regional clinics was implemented which required additional programming to access the data that had not yet been integrated into the institutional data warehouse. Additionally, some specific ICD codes were also updated during this time period. System changes are inevitable, as institutions maintain EHR systems and controlled terminologies evolve. Due to flexibility of the system design, we were able to resolve phenotype tuning issues and adapt to external and internal environmental changes smoothly.

Several concrete lessons were learned that are unique to comparing EHR with self-report data. First, record linkage can be problematic, even in cases where id numbers are used. [7; 8] Linked data should always be fact checked to make sure errors have not occurred. Second, phenotype definitions will evolve and change based on data source, date of collection and workflow or process of collection. Third, comparisons for events will cause a multiplicity of “no match” conditions (e.g. hospitalizations and procedures can easily lead to a large *all possible combinations* problem if the date windows are not sufficiently tolerant). Lastly, the permutations of possible outcomes (discrepant, possible, and not discrepant) must be very carefully considered. These conditions were discussed on multiple occasions as new information came in from phenotype runs and were compared directly against data in Epic®.

This work has provided a window into the quality of EHR data through the design and implementation of a near-real-time data quality measurement system while supporting study operations for informatics and research. While the architecture was designed for the University of Arkansas’ environment it may be adapted and generalized to work at other institutions and for other data sources.

5. Conclusion

It is well-known that the quality of EHR data varies from institution to institution. The implementation reported here identified additional challenges in acquisition and assessment of discrepancies between EHR data and patient self-report data. Even with well-defined approaches a significant amount of effort to adapt and keep up with institutional changes and handle unpredictable quality issues was needed. The work reported here required a team- based approach with the technical staff, informaticists, clinicians and other subject matter experts. Observations and lessons learned from this implementation may inform others as they embark upon use of EHR data during and to support clinical and informatics studies.

Negation Detection for Clinical Text Mining in Russian

Anastasia FUNKNER^{a, 1}, Ksenia BALABAEVA^a, and Sergey KOVALCHUK^a
^a*ITMO University, Saint Petersburg, Russia*

Abstract. Developing predictive modeling in medicine requires additional features from unstructured clinical texts. In Russia, there are no instruments for natural language processing to cope with problems of medical records. This paper is devoted to a module of negation detection. The corpus-free machine learning method is based on gradient boosting classifier is used to detect whether a disease is denied, not mentioned or presented in the text. The detector classifies negations for five diseases and shows average F-score from 0.81 to 0.93. The benefits of negation detection have been demonstrated by predicting the presence of surgery for patients with the acute coronary syndrome.

Keywords. clinical texts, medical records, electronic medical records, natural language processing, negation detection, Russian, anamnesis

1. Introduction

An electronic medical record (EMR) contains records in natural language, for example, life and disease anamnesis, protocols of surgeries, examination or discharge reports. Developing predictive modeling in medicine requires additional features, and not only strictly structured ones, such as blood tests, patient metrics, etc. For the English language, there are many tools for labeling text, extracting entities, disease's cases, temporal and negation detection (UMLS, UIMA, IBM Watson, Apache Ruta, etc.) [1–4]. However, most of the tools are now impossible to adapt to the Russian language because a word corpus of medical texts has not yet been compiled. There is a small one based on 120 records with labeled diseases and their attributes (complications, severity, treatment, etc.) [5,6]. But this corpus is compiled on the records of one medical centre and for patients with a limited set of diseases, and therefore it is difficult to use it for automatic text labeling of other medical centres. Thus, our team aims to develop a system of four modules to solve problems of misprints in medical terms, negation, temporality, and experimenter detection (see Figure 1). This paper is devoted to a module of negation detection.

It is accepted that any condition or disease is sought by the occurrence of synonyms-terms in medical history, anamnesis, etc. However, the presence of such a term may also indicate that the patient denies the disease. In Russia, healthcare providers often ask patients after admission to the hospital about strokes, heart attacks,

¹ Corresponding Author, ITMO University, 49 Kronverksky Pr., St. Petersburg, 197101, Russia; E-mail: funkner.anastasia@itmo.ru, funkner.anastasia@gmail.com.

and high blood pressure in the past, as this may affect the course of treatment. As a result, in disease anamnesis, phrases like “MI in the past denies” (Myocardial Infarction), “there was no increase in blood pressure”, “without a history of hypertension”, “diabetes denies” can be often found.

The above-mentioned problem is called negation detection in texts. One of the first algorithms NegEx was proposed by Chapman et al. in 2001 and was based on rules [7]. Subsequently, syntax-based methods for the English language were developed [8,9]. Goryachev et al. implemented four methods for detecting negations and compared them using three sets of clinical records in English [10]. NegEx showed the best accuracy [7]. Thus, most of the approaches found for identifying negations are developed with grammatical rules for the English language.

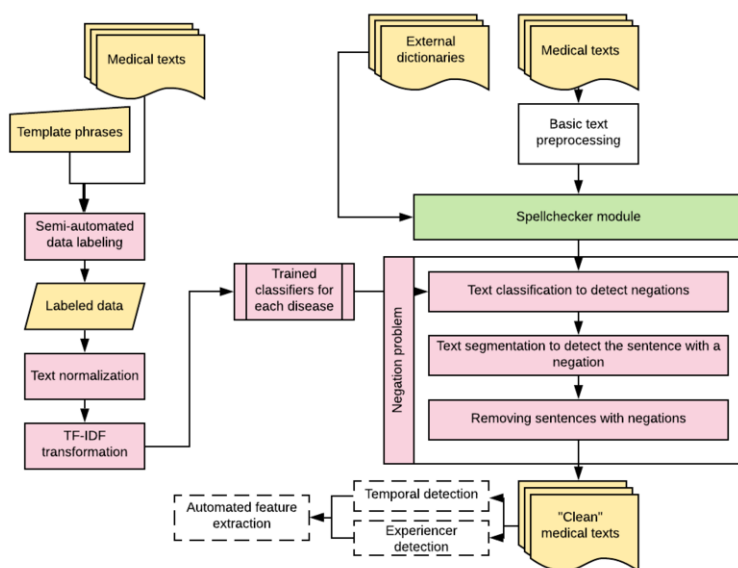

Figure 1. Modules of spelling correction and negation detection. Pink blocks indicate methods which are described in this paper. Green blocks are developed and implemented by colleagues. Dashed blocks indicate methods that are just being developed.

2. Method

In this research, we used a set of anonymized 3434 EMRs of patients with the acute coronary syndrome (ACS) who admitted to Almazov National Medical Research Centre (Almazov Centre) during 2010-2015. Disease anamneses are one of the most unstructured records (free text without any tags; each physician writes as he/she wants), and therefore we used them to demonstrate our approach.

Our approach to detect negations is machine learning based on multi-class classification. In Figure 1 the main steps are presented on how to train a negation detector and use for new data sets. Firstly, clinical texts should be annotated with 3 labels for each specific disease: ‘-1’ means ‘the disease is denied’, ‘0’ means ‘the disease is not mentioned in the text’ and ‘1’ means ‘patient has this disease’. We suppose to annotate the whole anamnesis with these labels because the classifier will be

able to learn an additional context which follows the disease. The two problems are possible: the disease can relate to a patient’s family members (label with 0) and there can be two descriptions about patient’s condition in different moments of her or his life (label with 1). We use semi-automated labeling with phrase search because the provided anamneses can be written in a similar format by the same doctor and it is possible to find repeated phrases.

Secondly, annotated anamnesis is normalized with pymorphy2 module which can be used for Russian and Ukraine [11]. Term frequency – Inverse document frequency (TF-IDF) transformation makes commonly used words less weighted in word corpus (prepositions, pronounce, etc.). TF-IDF vectors are used to train, tune and chose the best classifier. In consequence of cross-validation experiments, based on decision trees a gradient boosting classifier shows the best result with F-score. Thus, we trained five classifiers for detecting arterial hypertension (AH), myocardial infarction (MI), stroke, diabetes mellitus (DM) and angina pectoris (AP) (see Table 1). Using negation classifiers is crucial for stroke, MI and AH. For MI and AH, the classifiers learn context and help find additional cases of these conditions. Table 2 includes the most import phrases for detecting MI which are disease terms and possible treatment (surgery and medications).

When the negations are detected, each sentence of the anamnesis is labeled as containing or not containing negation using a logistic loss [12]. Sentences or their parts with negations are removed from anamnesis so that these texts can be used to build other models and consider only the patient's existing conditions, for instance, for topic modeling.

Table 1. The comparative results for negation classifiers (F1 – F-score). False positives are anamneses which were detected with ‘1’ and ‘-1’ using a term search and a negation classifier respectively. False negatives were detected with ‘0’ (terms not found in a text) and ‘1’ with the same methods.

Disease	Number of annotated anamneses	F1 for ‘-1’ labeled	F1 for ‘0’ labeled	F1 for ‘1’ labeled	Macro average F1	Total accuracy	Number of false positives (%)	Number of false negatives (%)
stroke	648	0.96	0.96	0.78	0.9	0.93	0.15	0.00
MI	897	0.95	0.5	0.97	0.81	0.96	0.07	0.15
AH	1167	0.88	0.59	0.96	0.81	0.93	0.08	0.20
DM	239	0.95	0.93	0.91	0.93	0.93	0.02	0.00
AP	864	0.67	0.91	0.98	0.85	0.95	0.02	0.01

Table 2. Feature importance (FI) of words and phrases which are used to define the presence of disease in an anamnesis.

Russian phrase	English phrase	FI	Class	Comments
оим	AMI	0.052	1	Abbreviation: Acute Myocardial Infarction
ибс оим	IHD AMI	0.042	1	Abbreviation: Ischemic Heart Disease. IHD includes myocardial infarction.
миокард отрицать	myocardial deny	0.041	-1	Patient denies MI
отрицать	deny	0.035	-1	Patient denies an acute condition
миокард ранее	myocardial early	0.027	1	Indicates myocardial problems previously
нижний	low	0.022	1	Indicates the localization of AMI
провести стентирование	perform stenting	0.016	1	Stenting is a surgery performed after AMI.
ознакомить	provide	0.015	0	Indicates anamnesis without a medical history

передний	anterior	0.014	1	Indicates the localization of AMI Medicines that are used to treat AMI
анальгин	analgin, tramadol	0.013	1	
трамадол				

3. Results

To evaluate how the application of negation detection module affects predictive model performance we conduct experiments on 2 tasks: clinical episode outcome prediction and prediction of surgery for the patients suffering from ACS [13]. Usually, all information medics have about a patient by the time of arrival is clinical anamnesis in the natural text format. Therefore, we use it as input data to train machine learning models.

During experiments all the models parameters remain constant (for XGBoost: num. estimators = 500, max depth = 100, learning rate = 0.1, objective = binary logistic; for Random Forest: max depth = 100, num estimators = 500, criterion = 'gini', min. samples split = 2, min. samples leaf = 1; for k-nearest neighbors model (KNN): num. neighbours = 10, weights = 'uniform'). The only change is in the input data for the fixed feature set: we use diagnosis features collected from clinical texts using regular expressions without negation detector and with the help of negation detector.

We evaluate the results on 33% test sample using the F1 score as a quality metric. The results are performed in Table 3.

Table 3. Evaluation of the negation detection (ND) performance on predictive tasks.

Task	Model	F1 without ND Text features	F1 with ND Text features	F1 without ND Text + other features	F1 with ND Text + other features
Surgery prediction	XGBoost	0.3755	0.5234	0.6941	0.6992
	Random Forest	0.3948	0.7110	0.7038	0.7128
	KNN	0.5091	0.5234	0.5851	0.5870
Outcome prediction	XGBoost	0.3234	0.3233	0.5208	0.5113
	Random Forest	0.3234	0.4229	0.4402	0.4569
	KNN	0.3234	0.3233	0.3428	0.3428

4. Discussion

According to the experiment results, we may conclude that the use of negation detector significantly improves the performances of XGBoost, Random Forest and KNN on the task of surgery prediction based on only text features. On the task of the outcome prediction, only Random forest improves. All other algorithms' results do not change. One of the reasons could be the need for additional information for the outcome prediction to improve since on current feature sample models predict the constant class for all instances and can't properly distinguish classes. For this reason, we conduct additional experiments and add other numerical features based on the first lab test the patients had. Lab tests for models are more significant than texts, therefore, the effect from the negation detection application is not such significant in this experimental set.

5. Conclusion

We demonstrated the procedure for training and using the negation detector on the example of disease anamnesis of patients with ACS. For five treatment-relevant diseases and conditions, the negation detector showed average F-score from 0.81 to 0.93 on the test sample. Also, the benefits of the negation detection were demonstrated with predicting the presence of surgery for patients with ACS. The developed and implemented module for detecting and removing negations is part of the application for processing clinical text. In the future, we plan to develop additional modules and make this application an indispensable part of data preparation and feature extraction for any predictive modeling.

Abstract. The amount of digital data derived from healthcare processes have increased tremendously in the last years. This applies especially to unstructured data, which are often hard to analyze due to the lack of available tools to process and extract information. Natural language processing is often used in medicine, but the majority of tools used by researchers are developed primarily for the English language. For developing and testing natural language processing methods, it is important to have a suitable corpus, specific to the medical domain that covers the intended target language. To improve the potential of natural language processing research, we developed tools to derive language specific medical corpora from publicly available text sources. In order to extract medicine-specific unstructured text data, openly available publications from biomedical journals were used in a four-step process: (1) medical journal databases were scraped to download the articles, (2) the articles were parsed and consolidated into a single repository, (3) the content of the repository was described, and (4) the text data and the codes were released. In total, 93 969 articles were retrieved, with a word count of 83 868 501 in three different languages (German, English, and Spanish) from two medical journal databases. Our results show that unstructured text data extraction from openly available medical journal databases for the construction of unified corpora of medical text data can be achieved through web scraping techniques.

Keywords. Natural Language Processing, Data Mining, Information Storage and Retrieval, Medical Informatics, Linguistics

1. Introduction

The amount of digital data derived from healthcare processes have increased tremendously in the last years [11]. Data available from healthcare sources can be roughly divided into two types: (1) structured data, namely information already organized into a known data model, for instance, results from psychological surveys or results of laboratory tests; and (2) unstructured data in the form of free-text data, medical images, or physiological signals. Examples for such free-texts are anamnesis records or discharge

¹Corresponding Author: Institute of Medical Biometry and Informatics, Heidelberg University, Im Neuenheimer Feld 130.3, 69120 Heidelberg, Germany; E-mail: matthias.ganzinger@med.uni-heidelberg.de.

notes and they are commonly written by healthcare professionals [7]. Dalianis et al. estimated that over 40% of healthcare data are unstructured [3]. It is often hard to use such unstructured texts for research and other analyses due to the lack of available tools to process and extract information. These tools must be tailored specifically for the medical field, and moreover, tailored for a specific language [3].

Nowadays, the way to analyze texts is using large corpora from which computers can learn the meaning of a word from its context, replacing former rule-based and feature-selection-based approaches [5]. However, availability of medical records for such research purposes is usually restricted due to privacy issues. Consequently, collecting biomedical texts extracted from journals have been proposed as a possible solution for the lack of resources [1, 12].

Natural language processing (NLP) is a sub-field of computer science, concerned with interactions between computers and human languages [4]. Some of the most important NLP applications in medicine are (1) detection of patterns in electronic health records (EHR) (e.g. detection of healthcare associated infections, adverse drug events or cancer symptoms); (2) text summarizing and translation of EHR; and (3) automatic codification [2]. While there are successful applications of NLP in the medical field [6, 13, 9], the majority of tools used by researchers are developed for the English language [8]. Therefore, creating tools and training corpora for languages different to English are valuable contributions to empower NLP of clinical sources in non-English speaking countries. To improve the potential of NLP research, especially for non-English languages, we developed tools to derive language specific medical corpora from publicly available text sources. Specifically, we focus on Spanish and German texts.

2. Methods

In order to extract medicine-specific unstructured text data, openly available papers from biomedical journals were used. The general process was divided into (1) web scraping of the database to download each of the articles contained in the website, (2) parsing of the raw downloaded data to consolidate it into a local standardized repository, (3) descriptive analysis of the content, and (4) the release of the data to the scientific community. A general overview of the workflow is summarized in Figure 1. The entire pipeline was developed in the Python² programming language.

Figure 1. Overview of our proposed workflow to generate corpora from medical journal databases.

²Python - <https://www.python.org/>

2.1. Web scraping

Web scraping is a technique to extract automatically data from websites. The package Scrapy³ was used to develop a script, which navigates through the database and downloads every article in XML format.

The recursive algorithm first searched for a medical journal in the index of the database, then inside the journal looked up for the volumes available, and finally the script searched for all the articles inside that volume and downloaded the XML file associated with the article.

2.2. Parsing of the raw data and corpora consolidation

For parsing raw XML files, the package BeautifulSoup⁴ was used. Additionally, we extracted the following attributes: title, language, abstract, day of release and journal / meeting name.

The parsed articles were then consolidated into separate corpora based on the language in which the article was written. Each corpus was word tokenized using the NLP framework Spacy⁵.

2.3. Descriptive analysis

For the exploration of the corpora, each corpus was summarized by (1) the number of articles that is composed of, (2) number of word tokens, and (3) vocabulary size counted as the number of different words. To compare each of the corpora, we first deleted stop-words from the text using the list provided in Spacy and then frequency of appearance of each word in each corpus was calculated.

2.4. Release

The corpora are made available to the research community as a package, which contains each article labeled with the language of the content. The code used to retrieve the corpora is available on a git repository⁶ and the corpora in a hosting platform⁷.

3. Results

In total, 95 737 articles were retrieved from the German Medical Science Database⁸ (GMS) and the Chilean Scientific Electronic Library Online⁹ (SciELO). After parsing the raw data, 1 762 empty articles were discarded. A division by language was made, finding that 63% of the articles were written in German, 24% in English, 13% in Spanish and <1% in French. The metrics of each corpus are described in Table 1.

A word frequency analysis was made for each corpus and ten of the most frequent words are summarized in Table 2.

10	durchgeführt (<i>carried out</i>)	time	forma (<i>form</i>)

4. Discussion

Current research on NLP in medicine mainly focuses in the English language; nevertheless there is an increasing effort in closing the gap of the development of NLP in languages beyond English [8]. Our work is a building block of a framework to retrieve medical unstructured text by the construction of biomedical corpora to support clinical text mining. Similar work was published by Soares et al. [10], but only SciELO database was scraped.

The toolset we describe in this manuscript has shown to be suitable for establishing generic medical corpora for multiple languages. To validate our approach we have queried a public Chilean and German database for medicine related publications. While we were focusing on German and Spanish texts, we retrieved a considerable amount of English texts because many the German site publishes in English as well.

Analysis has shown that the most frequent words conform across the corpora only partially (cf. Table 2). This result is to some extent unexpected, since scientific texts, as they are provided by the the underlying collections, typically share a very similar structure (IMRaD – Introduction, Methods, Results, and Discussion). While the reason for this finding needs further investigation, it might be due to differing focus areas in the collections. This result is supported by the figures shown in Table 1. Obviously, the GMS database contains shorter texts, possibly due to a large amount of conference abstracts published by them.

With a large amount of medical text data, the simplest model we can develop is a probability distribution, where we can predict upcoming words given a sentence. These models are essential in tasks where we have noisy and ambiguous inputs [4], as they oc-

cur, for instance, in spelling and syntax correction of clinical texts or speech recognition tasks for electronic health records (EHR).

5. Conclusion

The unstructured text data extraction from openly available medical journal databases for the construction of unified corpora of medical text data can be achieved through web scraping techniques.

Abstract. Processes like the care of type 2 diabetes mellitus patients require support by information systems considering the heterogeneity of the actors from different domains involved, enabling harmonization and integration of their specific methodologies and knowledge representation approaches towards interdisciplinary cooperation. Currently, the development of systems starts from the simplified information world, ignoring the aforementioned heterogeneity and specificity of real-world processes. This paper aims to demonstrate the feasibility of developing an adaptive, interoperable and intelligent system that supports the major aspects of type 2 diabetes mellitus care based on the Generic Component Model as formal methodology for modelling universal systems. The result is a deployable solution based on a formal representation of the diabetes care system, its objectives, and the intended business process. The implemented system enables reasoning over the data, inferring medical diagnosis. The effectiveness of the inference was evaluated, obtaining an F-measure of 0.89. The methods presented in this paper helps to build high quality models based on computation-independent aspects, which enable the construction of knowledge-based adaptive, intelligent and interoperable eHealth systems.

Keywords. Diabetes mellitus, Health information management, Ontology-based Systems, Systems architecture, Knowledge-based systems

1. Introduction

Currently, numerous software applications have been developed and implemented to support health care services. Few of them aim at achieving data interoperability, mapping

¹ Gustavo A. Uribe, ATLAS experiment, CERN, Espl. des Particules 1, 1211 Meyrin, Switzerland; E-mail: gustavo.uribe@cern.ch.

the structure of their data to different standards. Even fewer systems consider the concepts and contexts of the data represented, i.e., the knowledge of the actors and the interoperability problems associated with the heterogeneity of this knowledge. Therefore, most of the systems have difficulties to “understand” the data and to adapt them consistently and correctly to the different stakeholders. Improving health care services by interpreting data to perform conclusions and actions requires a specific level of system intelligence, especially needed in low and middle income countries where skilled human resources are limited.

The deployed methodology, i.e. the architectural model and framework, for designing and implementing a type 2 diabetes mellitus (T2DM) software system is based on the Generic Component Model (GCM) [1]. GCM allows the representation of any system architecture and the analysis and design of information systems. The GCM has been explained, discussed, used and compare in several papers, e.g. [1-4]. However, most of those papers focus on the principles GCM, without evaluating concrete software implementations. The proposed method allows the harmonization of the diversity of terms and concepts involved in health services by abstracting them. Thus, interoperability, collaboration and decision-making between health systems actors are demonstrated for a T2DM care scenario in the Colombian context. The paper’s main objective is to demonstrate the feasibility of developing an adaptive, interoperable and intelligent T2DM care system based on a formal methodology for modelling of systems and their ontological representation. The T2DM scenario was considered because of its high prevalence, 8.5% in 2014 [5], and its complex management due the required collaboration of many health professionals from different domains.

2. Methods

The methodology followed in this work is based on the GCM framework for analysis, design and implementation of the systems, providing a generic abstract architecture for each domain-specific aspect of the system instantiated by domain-specific ontologies. The obtained model addresses three domains, viz. the medical, policy and resource domain. The upper-level ontology BioTopLite [6] was deployed to harmonize the different domains’ concepts and knowledge. It provides high compatibility with the top-level ontology BFO [7], and it additionally considers some relevant and general aspects of the biological domain.

Ontology languages such as the Web Ontology Language (OWL) were used to represent architectural and static aspects of the system such as the generic system description and the description of the glycaemic control use case. Functional or dynamic aspects of the system are modelled by the Business Process Modeling Notation (BPMN) [8]. The business process model describes the expected behaviour of a business system and allows controlling, monitoring or implementing the ongoing processes.

Policies and rules governing the system for the glycaemic control use case were formally described using the SPARQL Inference Notation (SPIN) [9]. SPIN is a general purpose, standardized, and broadly accepted rule language that allows the definition of rules related to ontology classes. Now, the computation-independent T2DM care system was completely modelled. Based on this description, the software development process was performed according to the ISO 10746 RM-ODP [10] and its viewpoints as defined in the GCM. The output of this process is the specification of the information technology (IT) solution and, finally, the running application system.

3. Results

Generic and specialized architectural models of the system have been explained in [11-13]. For each GCM viewpoint, the models are adapted according to some inputs required for the development process [1, 13]. The Business View corresponds to the architectural models expressed using OWL and SPIN, and semi-formal models of the behaviour represented using BPMN. The Enterprise View defines the roles, activities and policies statements of the specified system [10]. The actors' roles in the system can be classified into: the categories of health organization staff, the self-care actor, the organizational administrator, and the resource chief. The roles have been derived from the International Standard Classification of Occupations [14]. The Information View represents in a platform-independent way the semantics of information [10]. It is defined in the ontology, but the datatypes of the information are not. In our approach, the entities representing data are *bt12:InformationObject* individuals. These entities are the only ones that use datatypes in a computational sense. The Computation View describes the functional decomposition of the system [10]. A functional decomposition was performed according to the general information cycle for any collaboration [13]. Five generic components has been defined: the data storage, the data interpreter (processing the data according to the formalized knowledge), the data mapper (maps the information to the knowledge of specific actor), the planner (decide the plan to be followed), the execution controller (assist the actors in the plan execution), and the execution listener (obtains new data after the plan execution). Additionally, some support components an execution engine, the reasoner, and the user interfaces are defined. The Engineering View describes the platform-specific infrastructure that supports the computational view. In our implementation, the system was deployed in four devices, the self-care device, the health professional device, a node including most of the computational components, and a node including the data storage. All are connected by Internet Protocol version 4 and HTTP. Finally, the Technology View describes the implementation of the system in terms of a configuration of technology objects representing the hardware and software components of the implementation [10]. In this view, the technologies used to implement the functional components are selected. For the execution engine functional component, the CamundaBPMN version 7.3 was selected. For the reasoner component the SPIN Rule Reasoner in its version 1.4 was deployed, and for the data storage the Virtuoso Openlink Server version 6.1 was used. The other functional components have been implemented using the Spring Framework version 4.1.7, available as open-source projects [15].

For evaluating the proposed system, a quantitative formal experiment was performed. Effectiveness is quantified using precision, recall and F-measure metrics. The hypothesis of the experiment is that the F-measure of the system's diagnosis is higher than 0.71, it is the average of the algorithms C4.5 and CART evaluated for the diagnosis of diabetes [16]. The specialist provided 20 anonymized medical records including its observations and decisions made for these patients. The medical records were structured according with the proposed information model, and then 1200 medical observations were obtained [15]. The prototype developed operates as an expert system for glycaemic control. after entering the 20 medical records, the system provides diagnostic suggestions. Table 1 compares the outcomes for one medical record. Some diagnoses corresponding to non-diabetic complications (e.g. chondromalacia of patella, mild malnutrition) were not included in the system. Other diagnoses have not been asserted due to the difficulty to infer them using the aforementioned rules, such as no chronic complications, uncomplicated diverticular disease colon, or probable primary hypothyroidism. Some

correct states about the patient have been added by the designed system (bolded in Table 1). These diagnoses were considered irrelevant by the specialist because they are not included in ICD10, which is used to classify the relevant medical diagnoses in Colombia. The mean F-measure obtained was 0.89, with a minimum value of 0.57 and a maximum value of 1. The F-measure has a standard deviation of 0.13. The mean precision is 1 and recall is 0.82. The significance of the results was evaluated with a one-sample T-test. The one-sample T-test resulted in an F-measure significantly higher than the threshold value (0.71) with a value of $p=0.00$.

Table 1. Diagnoses by physicians versus diagnoses by the system (underlined and bolded the differences)

Diagnosis by Physician	Diagnosis by the System
Type 2 diabetes mellitus	Type 2 diabetes mellitus
Peripheral diabetic neuropathy	Peripheral diabetic neuropathy
Overweight	Overweight
Metabolic syndrome	Metabolic syndrome
Hypertriglyceridemia	Hypertriglyceridemia
Raised fasting plasma glucose	Raised fasting plasma glucose
<u>Scleral and hypertensive cardiopathy</u>	South Asian central obesity
<u>Congestive heart failure stage II – C</u>	Decreased ankle reflex
<u>Coronary artery disease</u>	Medical alert – hyperglycemia
	Hypoesthesia
	Medical alert – hypertension

4. Discussion

The correct and formal description of domains and contexts through rules allows the adaptability of the system. For example, the presented system was developed using a description of the context of the Colombian health system, but it can be adapted to other health systems by the definition of their specific context. Furthermore, the software system is able to adapt to the physician's preferred language and methodologies including internal guidelines, measurement units, etc.

Contrary to the presented proposal, traditionally, the development team models the system by abstracting the types of information generated and shared during the business process. The resulting models are semi-formal descriptions of the system and are not intended to formally describe the system domains' knowledge, thereby preventing knowledge sharing and management including the deployment of best-of-breed expertise. Therefore, at least the following problems arise in traditional development processes:

1. The models are highly dependent on the knowledge of the development team. Different development teams provide heterogeneous models without a clear way of harmonization.
2. The models ignore essential concepts and knowledge of the business domain, as domain experts are usually not part of the team.
3. The models cannot guarantee correct inferences using logic rules.
4. Most parts of the models are specific for the correspondent business process, limiting the re-usability of components and reducing the chance of interoperability.
5. There is no a clear separation between the business domain description and the description of the information objects. That makes interoperability between information models difficult.

One limitation of the presented proposal is the medically relevant diagnoses of absence conditions, e.g. the diagnoses “No chronic complications” and “Uncomplicated diverticular disease colon”.

5. Conclusions

This paper presents the development of a software system and its evaluation process, starting from an abstract description of the real system considering computation-independent aspects up to a concrete ontology-based web application. This application follows medical guidelines, includes the data of the patients and suggests a precise diagnosis.

The paper testifies the feasibility to develop an adaptive, interoperable and intelligent T2DM Care System based on the GCM methodology and framework. The resultant software is available as open source in [15].

Optimization of Entropy-Based Automated Dyslalia Screening Algorithm

Emilian Erman MAHMUT^{a,1}, Dorin BERIAN^a, Michele DELLA VENTURA^b and Vasile STOICU TIVADAR^a

^aPolitehnica University Timisoara, Romania

^bDepartment of Music Technology, Music Academy “Studio Musica”, Treviso, Italy

Abstract. This paper presents the current state of progress of a project aimed at achieving an automated information entropy-based discrimination of phoneme mispronunciations in utterances of early school-age children. The introductory part briefly describes the dyslalia symptomology and the incidence of dyslalic disorders. This section also reviews the current challenges posed by the main research objective in other similar projects sharing the same objective and summarizes the current results thereof. The Material and Method section presents the conditions, the technology and the feature-extraction technique used in the experiment. The same section also describes the computation of the information entropy values of each analyzed speech sample. The highest match rate of 93.33% was achieved in the classification of words containing the phoneme /r/ in the initial position. A synthesis of the achieved results is provided in the Results section based on which conclusions are drawn and exposed in the Discussion and Conclusions section.

Keywords. Dyslalia, Information Entropy, Polynomial Trendline

1. Background

Dyslalia is the most frequent Speech Sound Disorder (SSD) among early-school aged children affecting mainly the phonetic tier of communication and it consists in the mispronunciation (distortion, omission, inversion or substitution) of speech sounds (phonemes). Its prevalence indicator for Romanian children is 13% [1] and its incidence is on a global ascending trend. Unless diagnosed and treated in due time, dyslalic disorders may have a dramatic impact on children's school performance and even lead to behavioral disorders. From a neuroscience perspective dyslalia has been linked to right-brain dominance and left-handedness and roughly a quarter of dyslalic subjects are affected by dyslexia-dysgraphia [2].

Phonological assimilation, which is both progressive and regressive within an utterance, poses a major challenge to the attempts to devise mathematical models for phoneme classification. It follows that the phonetic context of a given target consonant is of utmost importance for rigorous analysis of its articulation.

There are several projects aiming to provide a computerized solution for the discrimination of misarticulated phonemes. Logomon [3] is a complex speech therapy

¹ Emilian-Erman MAHMUT, Politehnica University Timisoara, P-ta Victoriei no. 2, Timisoara, Romania; E-mail: emilian.mahmut@aut.upt.ro.

software for Romanian equipped with a fuzzy-logic based expert system dedicated to pronunciation assessment. No specific pronunciation assessment results are provided by the authors, but human intervention (phoneme scores assigned by the Speech Therapists) is massively required to achieve such objective. Intelligent System for Impaired Speech Evaluation [4] focuses on the pronunciation of consonant /r/ in Romanian in an attempt to generate real-time numerical information on mispronunciations by analyzing Mel-Cepstral coefficients extracted from phonemes and by computing, for each item of the unclassified classes (test data), the (Euclidian) distance to each item in the known (learning) data classes (manually selected correct or incorrect pronunciations). The related distances are ordered and the final decision is made by using a K-Nearest Neighbor (KNN) algorithm. This study reports a 78% match rate for a K of 11. Self-Organizing Maps for Identifying Impaired Speech [5] describes an automated method for the discrimination of heavily impaired pronunciations of /r/ in Romanian based on Kohonen neural networks. The algorithm uses the parameters extracted from the alternating component of the signal envelope as feature vectors in a neural network-based classification stage. The study reports an 82.5% match rate with the best mispronunciation classification results within the 1000-1500 training ages range and concludes that mispronounced speech sounds have a tendency to organize on a single neuron while correct pronunciations spread on several map nodes. Vocaliza [6] is a computer-based speech therapy application for Spanish speaking children. Its phoneme mispronunciation module proposes a detection method based on feeding single phonemes (segmented from words uttered by children) to a phonetic decoder (automatic speech recognition algorithm). The speech sound discrimination scenario consists of 3 stages: identifying the phoneme-level confidence measure by using posterior probabilities resulting from a confusion network (CN) generated from the phone lattices (lattice compression algorithm), adapting the acoustic model by using Hidden Markov Models (HMM) trained on a Spanish language audio-record database containing 63193 words (Albayzin) and non-linear mapping of CN posteriors (confidence measures) to improve prediction as compared to the classification performed by non-expert human labelers. The authors conclude that the decision made by an expert (speech pathologist) will invariably have a subjective component. The study reports a match rate of 85.81% for the human labeling tasks. Human intervention is still required to a significant extent in order to reach efficient SSD assessment match rates enabling rigorous detection of phoneme mispronunciations.

The main objective of our research project is the development of a software solution for the fully automated entropy-based screening of dyslalic disorders in early school-age children. The screening system architecture is presented in [7].

2. Material and Method

An observational experiment was conducted on a target population of 30 children aged 5-7 from the Banatean National College in Timisoara (Romania), focusing on the pronunciation of the vibrant lateral consonant /r/ in initial, median and final position within the Romanian words: "RAFT" (shelf), "PARĂ" (pear) and "FAR" (headlight). The audio samples were recorded in the speech therapy practice using an Olympus LSP1 Linear PCM Recorder (PCM 44.1 kHz/16 bit). Each pronunciation was assessed by the speech language pathologist (SLP) so as to be compared with the results of the

screening application. The application was built in C# (Microsoft.NET) using Accord.NET audio processing libraries to display the polynomial trendline based on the positive amplitude values of the audio signal (Figure 1).

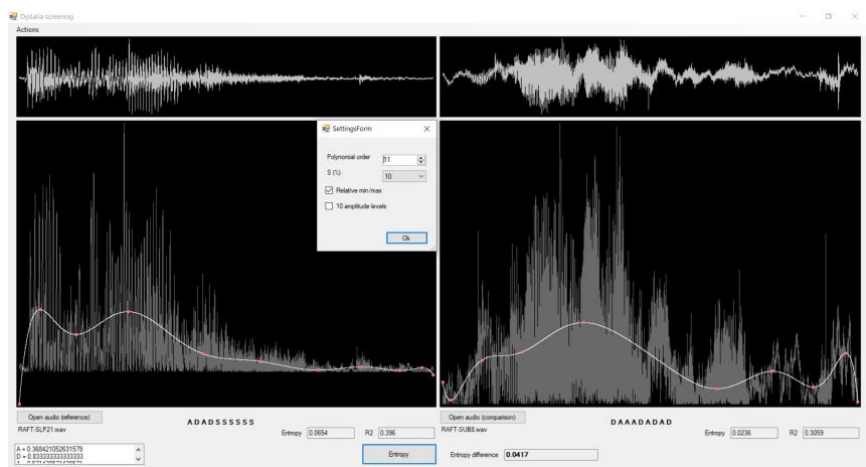

Figure 1. Dyslalia Screening Application

The algorithm extracts the polynomial trendline of a variable order (from 9 to 12) from the audio signal and describes its evolution by assigning 3 possible values to its peaks and troughs: A (ascending), D (descending) or S (stable, i.e. curve variation from previous value remains within a predefined range, in percentages of the max. amplitude value). A transition matrix shown in Figure 2 (Markov process) [8] is then filled in with such values (letters) for the reference signal (SLP’s pronunciation whose corresponding polynomial trendline has the highest R-squared value) and the test signal (subject’s pronunciation of the same word) taken together, e.g.: SLP’s pronunciation and Subject’s pronunciation. The probability of each alphabet letter is given by the quotient of the number of occurrences of the specific letter $n+1$ given another previous letter n (numerator) and the total number of occurrences of the specific letter in the 2 segments combined (denominator) [9]. The corresponding information entropy values for each segment are then calculated based on the probabilities provided by the transition matrix and compared. To have a drastic assessment of the test signal, the similarity threshold was set to a maximum value of 0.00099, therefore the test-signal entropy values belonging to the [0-0.00099] range were deemed to match the reference-signal entropy value, whereas test-signal entropy values of higher magnitude orders (i.e. in the [0.001 – 1] range) were labeled as mismatch (false positive or false negative cases).

	A	D	S		Alphabet	Total
A	2	5	0	A	7	
D	4	0	1	D	6	
S	0	1	5	S	6	
					19	

Figure 2. Transition matrix and alphabet

3. Results

Calculations were made based on the algorithm described above for 1440 values in all possible configurations (combinations of polynomial orders and S-letter ranges).

Table 1. Highest match rates for initial /r/

Initial /r/	Poly 9-S 15	Poly 10-S 2	Poly 10-S 5	Poly 11-S 10	Poly 12-S 15	SLP Opinion
Subject 1	-0.0099	-0.0614	-0.0125	0.0163	0.0049	Pararhotacism (/iaf-/)
Subject 2	0.0043	-0.0194	-0.0194	0.0102	0.0019	Rhotacism (/Raft/)
Subject 3	0.0057	-0.0617	-0.0703	-0.0218	-0.0137	Polymorphic (/rarf/)
...						
Subject 30	0.0019	-0.1449	-0.018	0.0341	0.0086	Rhotacism (/Ra:ft/)
Match Rate	86.66%	90%	90%	93.33%	86.66%	

The resulting match rate was compared to the SLP’s opinion on each analyzed utterance. The highest match rates achieved were: 93.3% for initial /r/, 80% for median /r/ and 83.3% for final /r/ as shown in Figures 3 and 4.

Figure 3. Initial /r/ results.

The highest match rate for the pronunciation containing the phoneme /r/ in the initial position (93.33%) was obtained using a polynomial order of 11 and an S-letter range of 10, while the best results for median /r/ (80%) were achieved using a polynomial order of 10 and an S-letter range of 5.

Figure 4. a) Median /r/ results b) Final /r/ results

For final /r/ the highest match rate (83.33%) was obtained by setting the polynomial order to 10 and the S-letter range to 10 or 15. It can be inferred from the synthetic diagrams (Figures 3 and 4) that an S-letter range of 2 produces the most stable results across the polynomial order range [9-12] in all three cases. The S-letter range of 15 generates the largest variation in the initial and final /r/ cases, while it remains fairly stable for the median /r/ case.

4. Discussion and Conclusions

The application computes and stores the R-squared value for each polynomial trendline to measure the goodness of fit of the model. Further analysis of such stored values is required to establish useful correlations. Higher polynomial orders (12 and above) generate poor match rates (33.33% to 70%) across the 3 cases, i.e. initial, median and final /r/.

The algorithm produced better results than previous studies and requires little human intervention.

Future work will focus on optimizing the audio signal quality (noise filtering) and segmentation by performing a normalized correlation of the pair of analyzed signals and using logatomes (monosyllabic pseudowords) with specific structures in terms of vowels (V) and consonants (C): VCV/CVC/CVV/VVC, where C stands for the target consonant. The inflection points of the polynomial trendline will also be considered for assignment of additional letters or sub-letters to be used in the transition matrix, by computation of the first and second derivatives.

Formant frequencies of the analyzed signals will also be explored to assess the possibility of devising alternative means to validate the segmentation described above.

Parallel Sentence Alignment from Biomedical Comparable Corpora

Rémi CARDON^a and Natalia GRABAR^a

^aUMR CNRS 8163 – STL, F-59000 Lille, France

Abstract. Parallel sentences provide semantically similar information which can vary on a given dimension, such as language or register. Parallel sentences with register variation (like expert and non-expert documents) can be exploited for the automatic text simplification. The aim of automatic text simplification is to better access and understand a given information. In the biomedical field, simplification may permit patients to understand medical and health texts. Yet, there is currently no such available resources. We propose to exploit comparable corpora which are distinguished by their registers (specialized and simplified versions) to detect and align parallel sentences. These corpora are in French and are related to the biomedical area. We treat this task as binary classification (alignment/non-alignment). Our results show that the method we present here can be used to automatically generate a corpus of parallel sentences from our comparable corpus.

Keywords. sentence alignment, text simplification, classification

1. Introduction

Parallel sentences provide semantically similar information which can vary on a given dimension. The dimension on which the parallelism is positioned can come from many levels, here we are concerned with expert and non-expert register of language. The following pair of sentences illustrates this:

- Expert : *Drugs that inhibit the peristalsis are contraindicated in that situation*
- Non-expert : *In that case, do not take drugs intended for blocking or slowing down the intestinal transit*

Pairs differentiated by their degree of technicality can be used for text simplification. The purpose of text simplification is to provide simplified versions of texts, in order to remove or replace difficult words or information.

Automatic text simplification can be used as a preprocessing step for NLP applications or for producing suitable versions of texts for humans. In this second case, simplified documents are typically created for children [1], or for people with mental or neurodegenerative disorders [2].

Helping patients to better understand medical and health information is an important issue, which motivates our work[3].

In order to perform biomedical text simplification, we propose to collect parallel sentences, which align difficult and simple information. We can exploit an existing monolingual comparable corpus with medical documents in French [4]. The corpus is composed

of documents created for medical professionals and documents created for patients. The purpose of our work is to detect and align parallel sentences from this comparable corpus. We also propose to test what the impact of imbalance on categorization results is: imbalance of categories is indeed a natural characteristic in textual data.

The existing work on searching parallel sentences in monolingual comparable corpora indicates that the main difficulty is that such sentences may show low lexical overlap but be nevertheless parallel. This task is usually explored in general-language corpora and performed as assigning a similarity score from 0 to 5[5]. Among the exploited methods, we can notice lexicon-based methods which rely on similarity of subwords or words from the processed texts or on machine translation [6]; knowledge-based methods which exploit external resources, such as WordNet [7]; syntax-based methods which exploit the syntactic modelling of sentences. [8]; or corpus-based methods [9]. There is no existing work on building a corpus for text simplification in the biomedical domain.

2. Method

We use the CLEAR comparable medical corpus [4] available online¹ which contains three comparable sub-corpora in French. Documents within these sub-corpora are contrasted by the degree of technicality of the information they contain with typically specialized and simplified versions of a given text. These corpora cover three genres: drug information, summaries of scientific articles, and encyclopedia articles. The *Drugs* corpus contains drug information such as provided to health professionals and patients. This corpus is built from the public drug database² of the French Health ministry. The *Scientific* corpus contains summaries of meta-reviews of high evidence health-related articles, such as proposed by the Cochrane collaboration and the simplified versions that they provide[10]. This corpus has been built from the online library of the Cochrane collaboration³. The *Encyclopedia* corpus contains encyclopedia articles from Wikipedia⁴ and Vikidia⁵. Wikipedia articles are considered as technical texts while Vikidia articles are considered as their simplified versions (they are created for children from 8 to 13 year old). Only articles indexed in the medical portal are exploited in this work.

We exploit a reference dataset with sentences manually aligned by two annotators within this corpus.

2.1. Automatic Detection and Alignment of Parallel Sentences

Automatic detection and alignment of parallel sentences is the main step of our work. The objective is to assess whether two given sentences have the same meaning.

The reference data with aligned sentence pairs, which associate technical and simplified contents, are created manually. We have randomly selected 39 documents from the corpus. The sentence alignment is done by two annotators. This alignment process provides a set of 238 equivalent sentence pairs. The inter-annotator agreement is 0.76

¹<http://natalia.grabar.free.fr/resources.php#clear>

²<http://base-donnees-publique.medicaments.gouv.fr/>

³<http://www.cochranelibrary.com/>

⁴<https://fr.wikipedia.org>

⁵<https://fr.vikidia.org>

[11], before consensus. In order to perform the automatic categorization, we also need negative examples, which are obtained by randomly pairing all sentences from all the document pairs except the sentence pairs that are already found to be parallel. Approximately 590,000 non-parallel sentences pairs are created in this way. That high degree of imbalance is the main challenge in our work and we address it in the experimental design (sec. 2.2).

For the automatic alignment of parallel sentences, we use a binary classification model that relies on the random forest algorithm [12]. The implementation we use is the one that is available in scikit-learn [13]. The features we use are the following: number of common non-stopwords; percentage of words from one sentence included in the other sentence, computed in both directions; sentence length ratio; average word length ratio, total number of common character bigrams and trigrams, word-based similarity measure exploits three scores (cosine, Dice and Jaccard) character-based minimal edit distance, word-based minimal edit distance [14], syntactic token-based minimal edit distance; number of common CUI (we generate all the possible subsequences of words in both sentences and check whether they have a corresponding CUI in the UMLS/SNOMED lexicon [16]. We count the number of times that a same CUI appears in both sentences); WAVG and CWASA [17].

2.2. Experimental Design

We work on sentences that are equivalent (they both express the same meaning). 238 equivalent pairs were obtained.

We performed two sets of experiments:

1. We train and test the model with balanced data (we randomly select as many non-aligned pairs as aligned pairs), and then we progressively increase the number of non-aligned pairs until we reach a ratio of 3000:1, which is close to the real data ($\sim 4000:1$).
2. Then, for each ratio, we apply the obtained model to the whole dataset and evaluate the results. Note that the training data is included in the whole dataset, we proceed this way because of the low volume of available data.

This means that each model is evaluated twice : once on the test set, and once on the whole dataset. We only report scores for the aligned category. The results that are presented correspond to the mean values over the fifty runs. Finally, we apply the best model on another 30 randomly selected documents and manually evaluate the output.

3. Results

We present the results in Figures 1 and 2: The x axis represents the growing of imbalance (the first position is 1 and corresponds to balanced data), while the y axis represents the values of Precision, Recall and F-measure. Figure 1 presents the results for the experiments where we evaluate the model on the test set, Figure 2 presents the results for the experiments where we evaluate the model on the whole dataset.

We can observe that the use of balanced data provides very high results, both for Precision and Recall, which are very close to the reference data (> 0.90 performance). These good results in an artificial setting cannot be applied to the real dataset, as is indicated by the starting point in Figure 2

Figure 1. Evaluation on the test set.

Figure 2. Evaluation on the whole dataset.

4. Discussion

When the model is learned on a substantial degree of imbalance, the Precision score is high when that model is applied to the real data, which has a ratio of about 4,000:1. The recall value is also high, but since two thirds of the aligned sentences have been used for training, that good score should be considered cautiously.

For further evaluation, we randomly selected 30 pairs of documents to evaluate the performances of the models. We used the model that was trained at a ratio of 1200:1. In terms of precision, the model shows 98.75% on all the sentence pairs aligned (80 sentence pairs), including equivalence, inclusions and intersection. Only one result showed two unrelated sentences. Those results show that we have a model that can be used to automatically generate a parallel corpus with reduced noise, from highly imbalanced comparable corpora, for text simplification purposes.

5. Conclusion

We addressed the task of detection and alignment of parallel sentences from a monolingual comparable French corpus. We use the CLEAR corpus, that is related to the biomedical area.

We made observations on the effect of imbalance during training on the performance on the real data. We show that increasing the imbalance during training increases the Precision of the model while still maintaining a stable value for Recall.

We will use that model to generate a corpus of parallel sentences in order to work on the development of methods for biomedical text simplification in French.

Abstract. Clinical trial data collection still relies on a manual entry from information available in the medical record. This process introduces delay and error risk. Automating data transfer from Electronic Health Record (EHR) to Electronic Data Capture (EDC) system, under investigators' supervision, would gracefully solve these issues. The present paper describes the design of the evaluation of a technology allowing EHR to act as eSource for clinical trials. As part of the EHR2EDC project, for 6 ongoing clinical trials, running at 3 hospitals, a parallel semi-automated data collection using such technology will be conducted focusing on a limited scope of data (demographic data, local laboratory results, concomitant medication and vital signs). The evaluation protocol consists in an individual participant data prospective meta-analysis comparing regular clinical trial data collection to the semi-automated one. The main outcome is the proportion of data correctly entered. Data quality and associated workload for hospital staff will be compared as secondary outcomes. Results should be available in 2020.

Keywords. Data collection; Health Information Interoperability; Clinical trial as topic; Clinical Trial Protocols as Topic; eSource.

1. Introduction

Pharmaceutical industry is facing increasing costs for drug development [1]. The automatic transfer of data from Electronic Health Records (EHR) to Electronic Data

¹ Corresponding Author, Nicolas Griffon, Web Innovation Données, 33 Bd Picpus – 75012 Paris, France; E-mail: nicolas.griffon@aphp.fr

Capture System (EDC) has been identified as one partial solution to address this issue by reducing the burden of data entry and associated activities, like data monitoring and review by sponsor [2]. Moreover, such solution would drastically reduce the time to entry, which is still too high, even with incentive [3].

A recent literature review [4] identified multiple initiatives towards automated transfer from EHR to EDC systems. Most of these initiatives being monocentric, retrospective or based on only one EHR, the authors also stress out the need for further research to better evaluate the impact of eSource solutions on data quality and workload: some burdens might decrease (entry, quality assessment...) but some others will increase (application maintenance, semantic interoperability maintenance).

The EHR2EDC project [5] has received funding from European Institute of Innovation and Technology (EIT) Health. This project is led by Sanofi R&D, include in a consortium 3 other pharma companies (see Tab 1), one Clinical Research Organization (ICON), one health data technology company (InSite, a TriNetX company), 4 hospitals (see Tab 1), the French National Institute for Medical Research (Inserm) and the European Institute for Innovation through Health Data (i~HD, a not for profit organization). The aim of this project was making such transfer a reality, by overcoming technical, organizational and regulatory difficulties. Building on the already existing InSite solution (developed by InSite), that allows feasibility studies and provides support for recruitment, a new module was developed, that prefills the concomitant medication, local laboratory, vital signs and demographic sections of the eCRF, and sends this information, under the investigator control, to the trial sponsor EDC. After unit, component and usability testing, it is now necessary to evaluate this tool's performances (data transfer capacity, error rate in comparison with manual entry, acceptability with regard to process evolution). This work focusses on the design of the evaluation protocol allowing to assess the performance of an eSource solution and the application of this evaluation protocol in the EHR2EDC context within the TransFAIR study.

2. Methods

2.1. Individual participant data – prospective meta-analysis (IPD–PMA)

IPD meta-analysis is recognized by the Cochrane collaborative group as a 'gold standard' of systematic review [6], and some authors strongly advocate for prospective meta-analysis [7]. Even if this study is a proof-of-concept technology evaluation study, and not a clinical trial, it was decided to design it like an IPD–PMA, following as much as possible PRISMA-P [8][9] and MOOSE [10] statements. This design will ease later inclusion of data from other tests in other hospitals using an eSource solution.

A preliminary protocol was developed by Sanofi R&D and submitted for review and validation to the whole EHR2EDC consortium. Each hospital was allowed to modify the template in order to customize this protocol but agreed to share patient level data to the statistician in charge of the meta-analysis (not the data collected in itself, but rather the result of the comparison of paired data sets collected, either manually or semi-automatically).

2.2. Study design

The main idea of this evaluation is to take advantage of real ongoing clinical trials (support CT), by performing a semi-automatic data collection in addition, and independently, to the usual manual data collection (see Fig 1). Support CT will be conducted in a completely usual way, and will not be affected by the TransFAIR study. The data collected in this way are named "Manual Data". All the patient included in the support CT are eligible for inclusion in the TransFAIR study.

In parallel of each support CT, the EHR2EDC transfer module will be installed allowing direct use of EHR data under the supervision of clinical investigators or study personal in a mirror study. As support CT are ongoing, patients may have been included before the beginning of the TransFAIR study. To increase the amount of data collected, both prospective and retrospective data will be collected using the EHR2EDC transfer module according to the following steps:

1. The study coordinator / investigator will supervise the automated data collection. Through the module interface, (s)he will review, validate and transfer the data required by the protocol to the sponsor eSource database.
2. The sponsor will then reconcile the manual and eSource database to identify discrepancies and provide them to the study coordinator / investigator.
3. For each discrepancy identified, the study coordinator / investigator will go back to the source documents of both eSource and support CTs data in order to collect the real value of the information collected.
4. To the best of his/her knowledge and skills, (s)he will try to identify error causes amongst: (i) rounding error, (ii) transcription error, (iii) wrong data entry for Manual Data, and (a) modification of information during the transfer, (b) wrong information transferred, (c) user error with the new module (wrong patient, wrong visit or wrong data selection) for the eSource data.

For data outside EHR2EDC scope (e.g. pathology, medical history), Manual Data will only be counted – and considered correct.

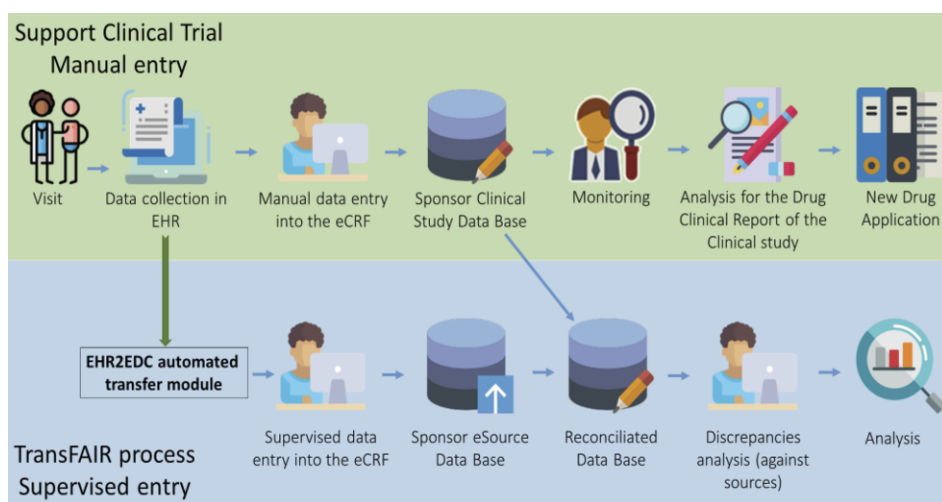

Figure 1. Support CT and TransFAIR study designs.

2.3. Outcomes

The main objective of the TransFAIR study is to assess the percentage of data accurately transferred (the number of data correctly transferred divided by the whole number of correct data – either manually or automatically entered). Secondary outcomes are:

1. Assessment of the percentage of target data points that can be accurately processed by the eSource solution. Computed like main outcome besides the denominator, that is restricted to data transferred.
2. Descriptive analysis of the identified types of inconsistency
3. Comparison of data management activities between the two processes assessed by the number of queries

Subgroup analysis will be performed on study site, type of protocol, medical specialty and data domain. For exploratory analysis, we will:

1. Compare entry error rates between arms, based on the discrepancy analysis, and try to identify some determinants of error rate: datatype (Boolean, text, date...), CDISC domain, data quality...
2. Explore more thoroughly the differences in queries between semi-automated and manual data entry.

2.4. Statistical analysis

We won't assess publication bias because of the prospective design of this meta-analysis. The heterogeneity between sites will be assessed using Cochran's Q and I square statistic. For primary outcome and 1st secondary outcome, proportion will be computed using a multi-level model to take account of inter site variance. A conditional logistic regression model will be used to compute OR estimate for entry error between arms. Once again, the inter site heterogeneity will be handled by a multi-level model.

2.5. Ethical concerns

Patients included in the support clinical trials will be asked if they consent to the reuse of their data in the context of the TransFAIR study. All the data shared between partners are shared with respect to the EU General Data Protection Regulation (GDPR).

3. Results

The TransFAIR study is being conducted using the proposed study protocol at 3 hospitals in parallel of 6 support clinical trials between mid-September and end-November, 2019 (see Tab 1). The 3 IRBs of the hospitals involved in the project approved both TransFAIR and support CT.

4. Discussion

Making the data interoperable between pharma and hospital world is a huge work that has been accomplished for demographic, local laboratory, medication and vital signs data

during the EHR2EDC project. It required the creation – to be published – of: (i) a FHIR common information model (CIM) – each hospital must be able to provide data in the CIM way, and, (ii) an important set of mappings between this CIM and pharma standards – derived from CDISC. This model makes different EHR and EDC systems interoperable.

Table 1. Description of support clinical trials

Running hospitals	Registration number ¹	Sponsor	Indication	Phase
APHP ² , 12Oct	NCT03767244	Janssen	Advanced prostate cancer	3
APHP, IRST-IRCCS	NCT03390504	Janssen	Advanced urothelial cancer	3
APHP	NCT03315143	Sanofi	Diabetes/cardiology	3
12Oct	NCT03284957	Sanofi	Advanced breast cancer	1b
12Oct	NCT03619213	Astra Zeneca	Heart failure	3b
IRST-IRCCS	NCT02516241	Astra Zeneca	Urothelial cancer	3

1: ClinicalTrials.gov identifier; 2: four APHP hospitals involved (Mondor, HEGP, Bichat, Lariboisière)

This study will allow the identification of data quality gaps in EHR, highlighting the data quality dimensions, as described by Khan et al., to put the focus on for the EHR2EDC scenario. The idea is to enhance the i-HD quality seal for Research Platforms [12] and to make it a requirement for any hospital to deploy and use any data transfer application between EHR and EDC.

This paper focused on the design of an evaluation protocol allowing the assessment of eSource solutions implementing large-scale connectivity between EHR and EDC systems. Results will be available in 2020.

Physician-Machine Interaction in the Decision Making Process

Saveli GOLDBERG^{a1}, Anatoly TEMKIN^b, Benjamin WEISBURD^c

Abstract. We propose an approach to decision support systems (DSS) that starts with the user first making their own unassisted decision α_U and providing this decision as an input to the algorithm. Then, if the decision based of machine learning (ML) disagrees with the user's initial decision, it iteratively works with the user to converge to a common decision or at least make the user reconsider input values that are inconsistent with α_U . We provide a detailed description of this approach along with examples, and then discuss potential benefits and limitations of this approach.

Keywords. decision support; machine learning; user interaction

1. Introduction

Success of artificial intelligence systems in medicine are amazing. However, the greater the accuracy of machine learning algorithms (ML), the greater the user's exclusion from participation in these decision-making processes. The danger of this is not only in the loss of responsibility for making the decision, but also in its correctness. The point is that machine learning uses a training sample collected in the past, while decisions are made in the present. But the past may be radically different from the present and the speed of changes may exceed the speed of additional training. Moreover, the machine's decision in any case is based on the patient's data provided by the physician, and therefore there is a danger of the preliminary physician decision's influence on the accuracy of this data. In psychology, this effect is called "Cognitive bias" [1]. Even in the absence of subjectivity in the assessment of the attribute's value there could be an error in the instrument's reading, in the measurement method itself, and in the natural fluctuations of the meter's readings. The best defense against these threats (the effect of detachment and non-availability of data) is seen in automating the explanation of the machine solution and the obligatory responsibility of a physician in the final decision [2]. These measures are indeed very helpful, but justification remains challenging, particularly for complex ML models.

Additionally, the better ML systems become, the more likely users will stop putting much effort into analyzing or critically evaluating the algorithms' decisions, even if automated explanations are also provided. Here we propose an approach that

¹ Saveli Goldberg, Ph.D., Radiation Oncology Department, Room 116, Massachusetts General Hospital, 10 Emerson Pl, Boston, MA, 02114. Email: sigoldberg@mgh.harvard.edu

introduces a meta-agent or decision support system (DSS) between the user and the ML algorithm [3]. This DSS restructures the interaction between a user and the ML to mitigate the potential loss of expertise and restore a fuller sense of responsibility to users. Central to this is that it requires the user to first make an unassisted decision and provide this as an input parameter to the algorithm before the algorithm generates its own automated decision. The DSS is trying to find "weaknesses" in the decision of the user. If the decision of the user continues to differ from the decision of the ML, the DSS helps the user to find the reasons for these discrepancies.

2. The Algorithm Overview

2.1 Definitions:

Let \mathbf{X} be the set of strings of length n of numerical or Boolean values and $D = \{\alpha_j\}$, $j=1, \dots, k$, is the set of possible decisions that could be made by the user or ML. Each string represents n parameter values. We define the decision function $f: (\mathbf{X}, D) \rightarrow [0,1]$, that maps an input $\mathbf{x}=[x_1, \dots, x_n]$ and a decision α to a confidence interval $[0,1]$.

Let $\mathbf{v} = [v_1, \dots, v_n]$ be the input provided by the user and α_u is the initial unassisted decision made by the user. The user also singles out parameters $[v_1, \dots, v_m]$, $m \leq n$, as being particularly important for making the decision α_u . ML finds $\max(f(\mathbf{v}, \alpha))$ for all α that belong to D . Let α_{ml} be the ML algorithm decision based on the user-provided input $\mathbf{v} = [v_1, \dots, v_n]$. The values x_i that are entered into the ML algorithm may be biased or erroneous, so we define $\Omega(x_i)$, $i=1, \dots, n$ as the set of values which are considered within the error bounds for x_i . The bias includes the uncertainty of a patient and the physician (i.e. the user). (the level of a patient headache or the degree of paleness are examples of a possible bias). When there is an uncertainty in assessing a parameter, we have a phenomena of "confirmation bias" and "selective perception" [1].

We introduce a parameter normalization x_i^{norm} for each i , based on four thresholds: $a_{0i}, a_{1i}, a_{2i}, a_{3i}, a_{4i}$ that are defined by a group of expert physicians.

$$\begin{aligned} x_i < a_{0i} & : \text{strong deviation } x_i^{\text{norm}} = 0 + x_i / a_{0i} \\ a_{1i} < x_i < a_{2i} & : \text{abnormal: } x_i^{\text{norm}} = 1 + (x_i - a_{1i}) / (a_{2i} - a_{1i}) \\ a_{2i} < x_i < a_{3i} & : \text{normal: } x_i^{\text{norm}} = 2 + (x_i - a_{2i}) / (a_{3i} - a_{2i}) \\ a_{3i} < x_i < a_{4i} & : \text{abnormal: } x_i^{\text{norm}} = 3 + (x_i - a_{3i}) / (a_{4i} - a_{3i}) \\ a_{4i} < x_i & : \text{strong deviation: } x_i^{\text{norm}} = 3 + x_i / (a_{4i}) \end{aligned}$$

Thus, normalized parameters will belong to five intervals: $[0,1]$, $[1,2]$, $[2,3]$, $[3,4]$, and the interval of numbers greater than 4.

Using this normalization we substitute $[x_1, \dots, x_n]$ for $[x_1^{\text{norm}}, \dots, x_n^{\text{norm}}]$. Now we define the distance between strings \mathbf{x} and \mathbf{y} in a standard way as

$$\|\mathbf{x} - \mathbf{y}\| = \sqrt{(x_1 - y_1)^2 + \dots + (x_n - y_n)^2}$$

To define a range of sub-normal (deviated) values, a team of experts empirically establishes acceptable parameter limits. They are determined for a certain combination of parameters and certain patients. If a parameter stays within the defined abnormal or normal range, no action is required. The strong deviation range covers all the sets of possible values beyond the abnormal values [4]. For example, if the body temperature is less than 35°C , then it is a strong deviation. If it is in the range $35^\circ\text{--}36^\circ$, then it is considered abnormal. If it is in the range $36.1^\circ\text{--}37.5^\circ$, then it is normal. If the range is $37.6^\circ\text{--}38.3^\circ$, then it is abnormal, and if it is more than 38.3° , then it is a strong deviation.

2.2 The Algorithm [5]:

- Step 1.** The user enters a string of data, $v = [v_1, \dots, v_n] \in X$ into the ML algorithm.
- Step 2.** The user makes an unassisted decision α_U and enters it into the ML.
- Step 3.** The user explains his or her decision α_U . The user singles out m out of n input values as being particularly important in making the decision α_U .
- Step 4.** DSS tests the physician decision. In this step the DSS checks whether α_U is stable when the input parameters are perturbed within the error bounds $\Omega(v_i)$. If ML comes up with the decision α_{ML} that is not equal to α_U , then go to Step 5. If ML comes up with the decision α_{ML} that is equal to α_U , then go to Step 7.
- Step 5.** DSS selects one or more “suspicious” parameters relied on by the user in making the initial decision. Since $\alpha_U \neq \alpha_{ml}$, DSS iteratively works with the physician. DSS could, at this point, just show the value of α_{ml} to the physician, but DSS specifically avoid doing this to prevent the physician from automatically changing his or her decision to α_{ml} . Instead, DSS use an indirect approach where it tries to find the parameter whose value v_i deviates the most from the typical value for the given α_U .
- There are some subtle details about this approach intended to make the user more willing to review his or her initial decision α_U . The First, DSS takes the user’s point of view as the starting point and works from there. The Second, DSS tries to only select parameters i that are greater than m , because the user doesn’t consider them as particularly important to α_U , so it may be more productive to point the user to inconsistency in these parameters rather than to inconsistency in parameters $1, \dots, m$ which the user marked as supporting α_U .
- Step 6.** DSS explains ML decision. As at this point the user’s decision still differs from the ML’s decision, the DSS attempts to explain the difference between the ML’s decision α_{ml} and the user’s decision α_U in a way that is intuitive for a user rather than in a way that is based on the ML’s internal representation. For this purpose, the DSS determines which input parameters were the most important for the ML’s decision. This can be done by finding the input vector z' which is the closest to the user’s input values v and which prompts the ML to change its decision from α_{ml} to α_U . A critical part of this step is that the distance between points v and z' is computed in the normalized parameter space (X^{norm}). The DSS can use a grid search to find points on the boundary between α_{ml} and α_U . Once z' is found, the parameters in which z' and v differ the most are recognized as the parameters being the most important to explain the difference between α_{ml} and α_U .
- Step 7.** A physician tests the ML decision and makes the final decision. A physician can modify v and observe corresponding decisions of ML. ML can in turn change its decision and provide an updated justification. Once the physician receives the ML decision for all the cases of interest, he or she makes the final decision.

3. Example Application

Some features of the proposed approach were implemented in the decision support system “Dinar-2” for the Center for Child Air-Ambulance Services in Yekaterinburg, Russia. One of the goals of the Center was to provide a remote consultation to doctors

in regional medical centers who treated seriously ill children. The Center has served the large geographic area, so for its air-ambulance services it would often take a long time to reach regional centers. A computerized decision support system had been key to the efficient operation of the Center. This system helped in diagnosing the type of pathology and in determining its severity. It has also assisted in selecting the best course of action and the healthcare center that is best suited for treating patients. Besides test results, the system had to consider a significant amount of subjective information about the patient's condition. This made the decision support task more complicated because the subjective information was susceptible to conscious and subconscious biases on the part of the reporting physicians. Specifically, these biases tended to skew the provided information toward making a patient's condition appear either severe than it was. Because of that, the Dinar-2 decision support system assigned an a-priori confidence interval to every input parameter that was based on subjective information. Then, the system perturbed the inputs within the bounds of these confidence intervals and checked whether its diagnosis was consistent with the diagnosis initially proposed by a physician. If, under these perturbations, Dinar-2's diagnosis of the patient's condition did not match that of the user, Dinar-2 would follow the proposed interaction flow (described in section II above) to clarify the diagnosis. After its initial deployment, several years ago, Dinar-2 was soon adopted by 39 air-ambulance centers across former Soviet Union, and has been use since then. For example, available statistics for the Yekaterinburg region for 2017 indicate that during that year the system assisted in evaluating 537 cases. In 131 of these cases (24%), effective remote diagnosis and consultation proved sufficient for resolving the patient's crisis, and the need to dispatch an air-ambulance was avoided [6].

4. Discussion

Can it be of interest to have only a user testing the machine or the machine testing a user? In our opinion, it can be. There are situations in which the degree of responsibility is so big that it is not desirable to directly indicate the machine's views. For example, this may occur when critical decisions about the patient care are to be made. Then, the parameters in which the ML and physician opinions differ are presented to the DSS for an increased scrutiny without ML being mentioned. A similar approach was used in [7]. Explaining an ML classifier's decision while treating the classifier as a black box was proposed before. However, our approach serves to provide explanations that are more intuitive to a physician because it uses the normalization of input parameters to map them into a space that is based on the way experts naturally think about these parameters. We would like to emphasize the importance of a physician to reach a conclusion before following up on a machine's suggestion. Requiring physicians to first reach their own decision serves to counteract the loss of physician's expertise and sense of responsibility that often occurs when users delegate decisions to the DSS. It prevents physicians from becoming complacent and motivates them to give more thought to their initial decision. It provides continued opportunity for users to revisit and refresh their domain knowledge. When a physician decision is different from the algorithm's, he or she reconsiders that decision considering parameters highlighted by the algorithm. In the end, it makes it more likely that the user will critically evaluate the machine's decision. Finally, if some of the inputs provided by the user are based on subjective information, it is likely that these will

contain biases that support the user's unassisted decision. By having access to this decision, the algorithm can take steps to correct these biases. Of course, all these benefits and the user-machine dialogue itself will not work if a user's solution is just a formality and a user will be waiting for a machine's solution before resorting to any actions. If the original decision is recorded, a physician will think twice before making it to avoid possible accusations of incompetency. Gaining experience of such a communication with the machine seems to significantly benefit each expert, but it also is useful for improving the quality of ML when working with an expert. Ongoing work involves testing this approach in medical diagnostic applications.

5. Conclusions

In conclusion, there are several benefits to structuring decision support systems in a way that makes the user provide their own unassisted decision to a decision support system as a first step. We expect this approach will increase the accuracy of the final decision and will serve to maintain and possibly even improve the expert users' domain knowledge.

Abstract. Predicting a patient's hospital length of stay (LoS) can help manage staffing. In this paper, we explore LoS prediction for a large group of patients admitted non-electively. We use information available at admission, including demographics, acute and long-term diagnoses and physiological tests results. Data were extracted from the electronic health records (EHR), so that the LoS prediction would not require additional data entry. Although the data can be accessed, the system does not present a unified view of the data for one patient: to resolve this we designed a process of cleaning and combining data for each patient. The data was used to fit semi-parametric, parametric and competing outcomes survival models. All models performed similarly, with concordance of approximately 0.7. Calibration results showed underestimation of predicted discharges for patients with high discharge probabilities and overestimation of predicted discharges for those with low discharge probabilities. The main challenges in operationalizing LoS predictions are delays in entering admissions data into EHR and absent data about non-medical factors determining discharges.

Keywords. Length of Stay, Bed management, Survival analysis, Medical data transformation.

1. Introduction

We develop and evaluate a Length of Stay (LoS) predictive model and use the prediction of individual patients' LoS from daily admitted cohorts to estimate levels of bed occupancy in the following days. Given the potential of LoS prediction to optimise hospital operations, many methods have been used to predict LoS including machine learning techniques, such as neural networks, logistic regression and regression trees [1] [2] [3], as well as statistical methods including negative binomial regression [4]. Here, we use survival models to obtain the probabilities of discharge of individual patients from daily admissions. Whereas many earlier studies have focussed on a restricted patient group, our aim is a model that can be applied to a wide range of patients.

¹ Corresponding author: School of Electronic Engineering and Computer Science, Mile End Road, London E1 4NS, Email: d.w.r.marsh@qmul.ac.uk

2. Background

The Acute Care Unit (ACU) in the Royal London Hospital provides short term treatment of patients aged 16 or older, admitted non-electively from Emergency Department (ED) or specialist clinics. After 48 hours patients are typically moved to specialist units or discharged. Patients are admitted to the ACU with a wide range of conditions, including injuries, acute health conditions and acute episodes of chronic conditions.

We used the data of the admissions to the ACU in the period 2013-17, consisting of 35,792 admission records for 20,836 unique patients – 52% women and 48% men, with a median age of 65 years. Median LoS was 4 days, with a mean of 8.4 days. 4.8% admissions ended with the death in hospital. There were 6,246 unique ICD-10 diagnostic codes in the sample. Patients' LoS was defined as the time interval between admission to ACU and discharge from hospital or death.

3. Methods

3.1. Data transformation

The Barts Health NHS Trust stores information about patient encounters in a Cerner Data Warehouse. Although the stored data is comprehensive, there are several challenges for building a data set for predictive modelling.

- Multiple identifiers are used: although there is a unique patient ID, every admission to a separate unit, including moves between units during a stay, is recorded with a unique encounter ID. The encounters that make up a hospital stay are not linked: a way to do this was found to assemble a patient's diagnoses, physiological results and treatment data for one admission.
- Data is entered at different times. Some data are entered into the electronic system in real-time during admissions but other data are recorded on paper and only entered into EHR at the end of patient's admission to the hospital. This can result in some of the data not entered into system or data recorded with errors.
- Codes and descriptions of diagnoses are stored together and there is no commonly used system to group individual diagnoses into clusters of clinically similar categories. A patient's diagnoses and physiological tests are often recorded with ED encounter ID, instead of ACU encounter ID.

We extracted demographic data from the ACU unit using patient and admission IDs and cleaned duplicates and errors. We extracted diagnoses data from all hospital's units using the patients ID in the demographic data. For each admission, multiple diagnoses were recorded. To obtain information about comorbidities, we extracted ICD-10 codes from all admissions before the current one, counting as comorbidities diagnoses that were recorded at least once in an earlier admission, excluding any from the latest hospital stay. However, only 33% of admissions were repeats; other patients were assumed free of serious comorbidities. We used the R *icd* package to classify ICD codes into comorbidities and calculated Charlson scores.

To cluster acute diagnoses, we extracted ICD codes and descriptions from current admissions and used R *erm* package, that groups clinically similar diagnoses. For the codes that could not be matched automatically, manual comparisons and corrections were made, from the ICD-10-CM 2014 to the ICD-10-CM-2019 codes, compatible with *erm* package. This method enabled all the common acute diagnoses to be clustered. Physiological tests results (blood tests and NEWS score), were extracted from all

hospital units from time interval *admission date minus one day* and *admission date plus two days*, to account for the tests performed in ED for patients admitted overnight and for repeated tests e.g. when the first sample has been compromised. This procedure resulted in missing values of 3%-5% for the most common tests (e.g. Hemoglobin, RBCDW) and up to 30% for less common ones (e.g. Bilirubin, Albumin). The missing values were imputed with population normal values.

In the last stage, we derived additional variables from the extracted data. For example, for *Kidney_problem* variable, we calculated for repeated admissions median Creatinine for patients' previous admissions and extracted dialyses and kidney transplant codes. We assigned the category 3 for admissions with kidney transplant recorded, 2 for ones with dialyses, 1 with the Creatinine level at a given admission at least 1.5 higher than median Creatinine from previous admissions and 0 if none applied. *Admission_number* and *Readmission_within_year* variables were derived to indicate if an admission was a consecutive one and if a given patient was often readmitted. The final data set consisted of 49 predictors.

3.2. Survival analysis

We developed and evaluated semi-parametric (Cox) and parametric (log-normal) models and Fine and Gray competing outcomes model. We set the evaluation time for 30 days and we defined the 'event' as discharge from hospital. Deaths during admission were right-censored for Cox and parametric models and a competing outcome for the Fine and Gray model. For Cox and parametric models, we fitted splines for continuous variables to account for non-linear relationships with LoS and we used backward variable selection algorithm to select significant predictors (p-value ≤ 0.05 for a global model).

4. Results

The hazards in the global Cox model for the selected variables were not proportional, and stratifying on non-proportional predictors did improve the proportionality result. Full Fine and Grey model did not converge, so this model was developed with the variables selected for Cox model. All models had similar concordance, presented in Table 1.

Table 1 Comparison of models' concordance.

Model	Concordance Index (AUC)
Cox	0.705
Log-normal	0.706
Fine and Gray model	0.703

Given the similar performance, we chose the Cox model for further analysis, as hazard ratios for discharge event could be directly obtained for Cox model regression coefficients, but not from Fine and Gray model [5] [6]. Validation of Cox model with resampling showed there was little overfitting. Predicting discharges by day 4 showed a mean prediction error of 0.033, with underestimation of discharges for the groups with high discharge probability and overestimation of discharges for groups with low discharge probability. Prediction on day 11 showed a slight overestimation of discharges for patients with medium probabilities of discharge, but the mean error decreased to 0.014. Figure 1 shows Cox model calibration performance on days 4 and 11.

4.1. Bed estimation

We calculated means of individual patients’ discharge predictions with confidence intervals (CI) to obtain the number of beds released from daily admissions. Figure 2 shows the predicted output for days 2, 3, 10,15 and 30 from admission of 14 patients. In the external sample of 180 admissions, for days 2 and 3, 66% of observed numbers of beds released were within predicted CI, day 10 - 81%, day 15 - 79% and day 30 - 75%.

Figure 1 Calibration of predictions on 4th and 11th day - Cox function.

Figure 2 Predicted and observed number of beds released on days 2,3,10,15 and 30.

Figure 3 Predicted and observed number of beds occupied from 3 consecutive admissions.

We used the model to predict bed occupancy from several consecutive daily admissions. Figure 3 shows the predicted and observed occupancy after 3 days from the admission on a given day, and the previous 2 days, for 180 admission days. The model predictions match the trends in the observed data. Perhaps because the Cox model does not account for deaths during the admission, the variation in larger in observed than predicted values.

5. Conclusions and future work

We have shown that patient information stored in EHR is sufficient for predicting LoS for a large group of patients with varying diagnoses admitted non-electively. This opens the way to make such predictions routinely without requiring additional data generation.

Building a data sets for modelling is challenging due to the form in which data is stored, but we showed that the necessary linking of records can be achieved so that a uniform dataset can be derived for all patients. We used LoS predictions for patients from daily admissions to estimate the bed occupancy on chosen days post-admission. Despite the suboptimal calibration group of patients with more extreme discharge probabilities, the model performed well for the prediction of beds released from daily admissions.

The next steps in operationalizing the model will be to investigate ways to facilitate real-time entry and access to data. Notably, the ICD-10 codes on which we rely are currently coded manually, but the use of machine learning methods (e.g. [7]) to automate coding has already been investigated and need not be perfectly accurate for LoS prediction. Sourcing comorbidity data for patients admitted to hospital for the first time also needs to be resolved; we plan to investigate the possible use of GP records for this. We will work to extend the prediction to elective admissions and investigate the hospital units to which patients are transferred when they are not discharged from the ACU. We will also investigate ways to incorporate the social factors in LoS analysis, as they can strongly influence a patient's discharge times and cannot be estimated from purely medical records. Finally, to transform the model into a decision tool, senior nurses and bed managers will be consulted on what predictions outputs are useful to support effective bed management.

Abstract. This study aimed to predict the duration of the postoperative in-hospital period in neurosurgery based on unstructured operative reports, natural language processing, and deep learning. The recurrent neuronal network (RNN-GRU) was tuned on the word-embedded reports of primary surgical cases retrieved for the period between 2000 and 2017. A new test dataset obtained for the primary operations performed in 2018-2019 was used to evaluate model performance. The mean absolute error of prediction in the final test was 3.00 days. Our study demonstrated the usability of textual EHRs data for the prediction of postoperative period length in neurosurgery using deep learning.

Keywords. Neurosurgery, Electronic Health Records, Operative Report, Machine Learning, Deep Learning, Recurrent Neuronal Networks, Artificial Intelligence

1. Introduction

Although machine learning is gaining special attraction in neurosurgery during the last years, the text analysis and natural language processing have rarely been used [1], [2]. The operative report is a document describing the details of surgical procedures in a patient's medical records. Written narratively in the majority of clinics, it undoubtedly provides certain knowledge when appropriately explored.

In-hospital stay duration is an indirect estimate of disease severity and healthcare expenses. We hypothesized that the information stored in operative reports could be sufficiently meaningful to predict the duration of the postoperative in-hospital period. To test that hypothesis in a pilot study the predictive model (recurrent neuronal network (RNN) - gated recurrent unit (GRU)) was previously built on 75 531 and tested on 26 123 operative reports [2]. We have shown that the postoperative period could be (to a certain extent) reasonably predicted using the textual description of the surgery, natural language processing, and deep learning. However, our study was limited by the data collected in a period between 2000 and 2017 years [2]. This study aimed to update the

¹ Corresponding author, N.N. Burdenko Neurosurgery Center, Moscow, 4th Tverskaya-Yamskaya str. 16, 125047, Russian Federation; E-mail: glebda@yandex.ru.

model developed previously and validate it on a new set of operative reports never seen by the model before.

2. Methods

In our previous study, the EHRs of N.N. Burdenko Neurosurgery Center was queried to select all operative reports with the corresponded length of in-hospital stay following surgery in the period between 2000 and 2017 [2]. In February 2018 the Hospital information system at N.N. Burdenko Neurosurgery Center was changed. The data on operative reports for a period between January 2018 and June 2019 were obtained from two sources: the old EHR (named “e-Med”; January - February 2018) and the new one (named “Asclepius”; February 2018 – June 2019) [3]. All the incomplete reports and cases with an inaccessible length of in-hospital stay were excluded.

In the current study, all the operative reports dated to 2000-2017 were split into primary surgical cases (the operations performed at our Center for the first time for patients) and repeated surgery, and the training samples were randomly generated from 75% of each subset. The testing samples constituted of the remaining 25% of documents in each category. The model was trained on primary and repeated surgery subsets independently, and its performance was compared in two testing samples accordingly. Finally, the model built on primary cases was fine-tested on operative reports for primary operations dated to January 2018 - June 2019. We did not consider the cases of repeated surgery for the final test due to the reasons explained in section 3.1.

2.1 Text preprocessing

All neurosurgical operative reports typed by neurosurgeons on computer keyboards were retrieved from EHRs. Corpus preparation was done using R programming environment (version 3.5.0) in RStudio IDE for MacOS (version 1.1.453). Raw textual data were preprocessed before fed into deep learning procedure as input:

- Transformed to lower case
- Tokenized with a space separator
- Proceeded by word embeddings

All the tokens generated from the original texts were mapped into numeric vectors from Euclidean space R^d when $d = 400$. These vectors were assumed to capture hidden information about a language, like word analogies or semantic relations between them. Distributed word representation was obtained from operative reports using the FastText library [4], [5]. The idea of that approach was in learning to predict a word from its context or vice versa. We considered the basic vector representations of character trigrams and expanded each word as the sum of the vectors of its trigrams. Then we built the constructions of skip-gram (a set of tokens that imply other tokens between them in an amount not exceeding the preset number) on these sums. Unlike the classic Word2vec and Glove, FastText provides the invariance of embedded tokens to word morphology since N-grams of characters are more common than whole words. As a result, the vector representations we obtained were expected to work efficiently with the rich-in-morphology Russian language.

2.2 The model architecture

The target variable was the postoperative period duration (number of days stored in EHR as integers). To process the operative reports, we RNN-GRU architecture proposed in our previous study [2], [6]. The logarithm of the hyperbolic cosine of the prediction error was used as a loss function since it is resistant to outliers and the second derivative of it exists. The adaptive gradient method RmsProp was utilized as the optimizer with the cut-off gradient value of the maximum norm equal to 1, and the cut-off gradient value outlying the range $[-1, 1]$ [4]. The activation function used was Exponential Linear Unit (ELU) [4]. The hyperparameters of the model were set by the grid search as:

- Batch size = 256 texts
- Dropout (for regularization) = 0.3

The model was trained using a Keras framework (keras.io) on the first 500 vector-represented tokens corresponding to documents. When the number of tokens was < 500 , the sequence was padded with a fixed token complementing sequence to 500.

2.3 The evaluation of model performance

Mean Absolute Error (MAE) was used to measure the quality of model prediction:

$$MAE = \frac{1}{n} \sum_{j=1}^n |y_j - \hat{y}_j| \quad (1)$$

where n – was the number of operative reports, y_+ – true length of the postoperative in-hospital period, y_- – the predicted duration of postoperative in-hospital stay [7].

The model was trained and evaluated within the Python (version 3.6) environment Jupyter Notebook for MacOS.

3. Results

In the period between 2000 and 2017, a total of 77 876 patients (avg. age 39 ± 20 years, males – 55%) underwent 104 506 neurosurgical operations. Initially, we obtained the complete uncorrupted operative reports for 101 664 operations and could verify the duration of postoperative period in 101 654 cases eligible for the inclusion. These texts consisted of 163 316 unique words or 36 438 unique tokens excluding stop-words and words appeared five and fewer times in all reports. The “primary surgery” subset included 75 652 reports (of which 56 739 documents were selected as a training sample). The “repeated surgery” subset included 26 002 reports (with 19 501 used for training).

3.1 Training and validation of the models

The characteristics of samples subsetting for this study and the corresponding measures of deep learning performance are presented in Table 1. The RNN-GRU was applied to “primary surgery” and “repeated surgery” datasets, resulted in MAE of 4.83 and 14.25 days respectively. The model trained on the first dataset outperformed the model previously built on the whole set of data for the period 2000-2017 (Table 1, primary

surgery vs. all reports). However, the result of prediction in the “repeated surgery” dataset appeared to be three times worse. Thus, the RNN-GRU built on the primary surgery dataset was considered as the final model.

3.2 Testing the final model

A total of 2034 operative reports for neurosurgical procedures was obtained from “e-Med” and 11 460 reports were retrieved from “Asclepius” for the period between January 2018 and June 2019. The test of a final model was performed on 11 968 complete operative reports for primary surgery with the known length of the postoperative period (a new testing dataset). The final model demonstrated MAE = 3.00 days (Table 1). The distinct result for “e-Med” data (n = 1 829, MAE = 2.85 days) appeared to be similar for that from “Asclepius” (n = 10 139, MAE = 3.03 days).

Table 1. The results of RNN (bidirectional GRU) testing on operative reports for primary and repeated surgery (n – number of operative reports, AE – absolute error).

	All reports* (2000-2017)	Primary surgery (2000-2017)	Repeated surgery (2000-2017)	Primary surgery** (2018-2019)
Sample size, n	101 654	75 652	26 002	11 968
Range of postoperative stay, days	0 - 1251	0 - 1251	0 - 746	0 - 199
Training sample size, n	75 531	56 739	19 501	11 968
MAE, days	7.78	4.83	14.25	3.00
Predictions with AE = 0 days	14.1%	20.2%	7.7%	20.1%
Predictions with AE ≤ 2 days	54.3%	64.9%	36.3%	67.5%
Predictions with AE ≤ 3 days	63.9%	73.7%	46.8%	78.5%
Median AE, days	2.19	1.52	3.86	1.51
Maximum AE, days	1070.51	731.37	730	174.52

* the results obtained from our previous study [2]

** a new testing dataset containing operative reports for primary surgery performed in Jan 2018 - June 2019

The absolute prediction error in the new testing dataset did not exceed three days in 78.5% of cases.

4. Discussion

To the best of our knowledge, this is the first study in neurosurgery aimed at prediction of the postoperative period based on unstructured medical texts. We chose the operative report for a pilot study to test the utility of textual records. A real-world model production, however, should consider the maximum structured and unstructured data available.

W. Muhlestein et al. (2017, 2018) predicted the length of in-hospital stay after brain tumor surgery using machine learning on non-textual data [8], [9]. Non-elective surgery, preoperative pneumonia, sodium abnormality, or weight loss, and non-White race were found the strong predictors of the prolonged in-hospital stay [8], [9]. In contrast, the results we obtained demonstrate the meaningfulness of narrative medical texts in these non-trivial predictions. The worse predictive capability of repeated surgery reports may indicate that the information essential for prognosis was not captured compared to primary surgery descriptions.

The lower MAE shown in the new testing dataset could be related to the shorter range of the target variable (compared to the development datasets). The high range of AE in all samples was caused by the broad initial range of postoperative periods due to outliers. The outliers in the training samples appeared to be extremely rare and better explained by occasional factors not related to the initial surgery directly, such as severe complications and repeated interventions. The EHR software change was not supposed to affect the results since the operative reports remained in textual format invariant to the system's interface.

The RNN-GRU model was efficient to predict the postoperative period with an acceptable error for the pilot study. However, the rationale for its efficiency should be unraveled in more details, e.g., applying the other machine learning methods, combining it with structured data analysis and considering neurosurgeon's expectation of a postoperative period length. Nevertheless, initial surgical exposure to the human brain appears to be a sophisticated factor itself which might determine the postoperative course and its length. The proposed model may still be improved by text preprocessing (e.g. lemmatization), adding convolutional neural networks layers, optimizing the architecture and training, testing alternative word embeddings (GloVe, Word2vec) [10].

5. Conclusion

Unstructured operative reports served as an informative source for prediction of in-hospital postoperative period in neurosurgery using deep learning. Our study demonstrated the usability of data stored in EHR as texts. *This research was supported by the Russian Foundation for Basic Research (grant 18-29-01052).*

Abstract. Integrating data from different sources into homogeneous dataset increases the opportunities to study human health. However, disparate data collections are often heterogeneous, which complicates their integration. In this paper, we focus on the issue of content heterogeneity in data integration. Traditional approaches for resolving content heterogeneity map all source datasets to a common data model that includes only shared data items, and thus omit all items that vary between datasets. Based on an example of three datasets in Systemic Lupus Erythematosus, we describe and experimentally evaluate a probabilistic data integration approach which propagates the uncertainty resulting from content heterogeneity into statistical inference, avoiding the need to map to a common data model.

Keywords. Probabilistic data integration, content heterogeneity, missing data, biomedical data harmonisation

1. Introduction

Integrating data from different sources into a homogeneous data resource creates powerful opportunities to study human health. However, disparate data collections are often heterogeneous, which complicates their integration.

Systemic Lupus Erythematosus (SLE) is a chronic autoimmune disease of unknown aetiology, affecting approximately 16,000 people in the UK. Through the MASTERplans programme [1] we have gained access to data from three cohort studies: Aspreva Lupus Management (ALMS), Lunar, and Exploratory Phase II/III SLE Evaluation of Rituximab (Explorer).

Content heterogeneity refers to the situation in which data items that are not equally represented across different data sources [2]. In the MASTERplans example, content heterogeneity occurs because Lunar and Explorer did not record age at onset of disease,

smoking status, white blood cells (WBC), platelets and lymphocytes, creating missing variables problems. Another form of content heterogeneity occurs because ethnicity was not recorded using the same categories across the three studies.

Traditionally, people solve these problems by mapping all datasets to a common data model. This model would only include variables that are present in all datasets, and, in case of granularity problems, categories that exist in all datasets.

2. Data and Method

First, we select all the datasets that are available and can enable us to answer the research question based on the description in the metadata. For the datasets that do not satisfy all the selection criteria concerning content heterogeneity we build predictive models that estimate the probability that these criteria are present based on other information that is available, using more complete datasets. The probabilistic relationship selection criteria are learned from other datasets. Our approach aims to preserve all the available information in the original datasets by translating content heterogeneity problems into missing value problems, and then solving these missing value problems using established methods (multiple imputation). The method assumes that naming differences are resolved beforehand, that the original datasets were sampled from the same population and that data are missing at random.

We applied our method to the three SLE datasets, to answer the research questions “does ethnicity predict response to treatment?” and “Finding the set of variables that best predict drug response”. For the first question a granularity problem occurred, and for the second question a missing variables problem occurred. For both solutions, we applied imputation using multivariate imputation by chained equations (MICE) [3] and a random forest approach called missForest [4].

In order to answer both questions, we included only ALMS-M (maintenance) information from the ALMS study data since we required patients to have a 12-month follow-up visit (with disease severity evaluated) which was not available in the ALMS-I set (which followed patients for only 6 months). We rescaled the first visit as zero days and calculated days for each following visit relative to that. For both questions were used datasets that included patients from all the three studies together, with multiple visits per subject. For the response measure only, in order to have only one visit per patient, we kept the visit that had the least absolute difference from 365 days (12 month). First question’s dataset consists of the 545 patients and 9 variables i.e., gender, age, ethnicity, height, weight, drug response (BILAGScore total), creatine, body mass index (BMI), and current treatment. Content heterogeneity occurs because ethnicities’ levels are not the same across all the sources. Ethnicity in ALMS has 4 levels, i.e., ‘Caucasian’, ‘Asian’, ‘Black’, and ‘Other’, where ‘Other’ are also different levels of ethnicity. On the contrary, ethnicity’s levels in Lunar and Explorer are ‘Caucasian’ and ‘Black or African American’. Therefore, in ALMS, ethnicity’s granularity is very high. For the granularity problem we add a categorical variable that classifies patients based on the ‘Other’ ethnicity. With this additional variable we eliminate misclassification.

The dataset with the missing variables problem contains not only the initial variables mentioned earlier but also smoking status, lymphocytes, WBC, and platelets. Missing variable problem occurs because these extra variables were included only in Lunar and Explorer data. We remove records for 7 patients with missing value for height and 9 with

missing creatine leading to 530 patients. This way makes it better and clearer to understand how the method works in application.

The chosen parameters for missForest imputation are 100 trees and a maximum of 50 iterations for both research questions. For MICE the chosen parameters are 30 and 20 imputed datasets, 50 and 40 iterations, and 10,000 and 15,000 seed for the research questions respectively. At the end, we fit linear regression models to the complete datasets that resulted from both imputation methods.

3. Results

In Table 1, we see the coefficients for the linear regression model that estimates the drug response based on ethnicity. We compare the coefficients from both imputation methods; MICE and random forest. Table 2 shows the coefficients for the linear regression model that estimates the drug response based on ethnicity, gender, smoking status, BMI, treatment, creatine, lymphocytes and platelets. Figure 1. shows the distributions

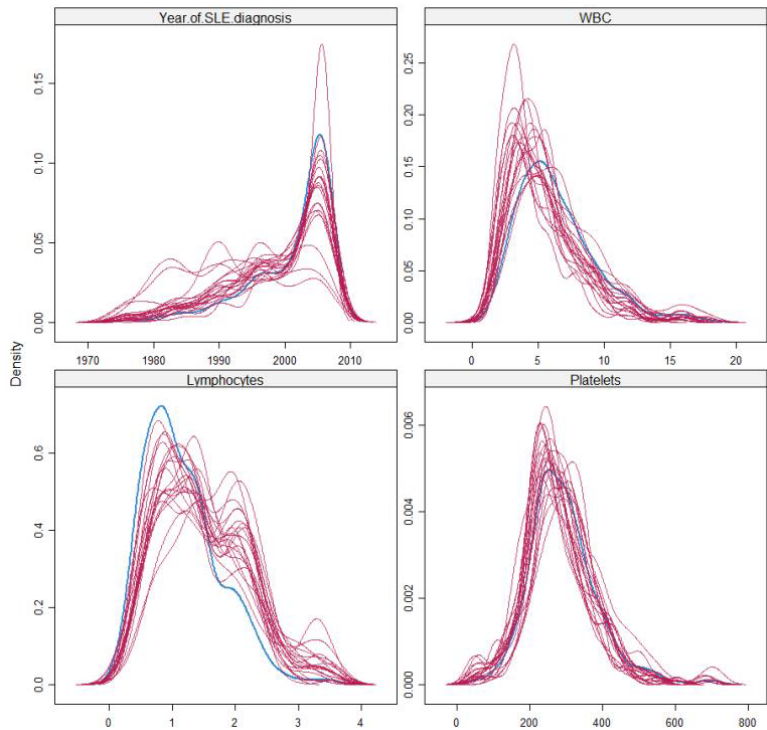

Figure 1. Density plots for year of SLE diagnosis, WBC, lymphocytes and platelets, in missing variables problem. Blue line shows the observed data and the red lines the imputed data from each of the imputations in MICE.

4. Discussion

The impact of ethnicity on drug relationship has the huge potential of achieving and improving the efficacy of results in precision medicine and differences in recommended drug doses [5, 6]. In table 1 we see that ‘Eritrean’ is significant and it implies that ethnicity is associated with drug response. Concerning the imputation methods, MICE did not have any misclassifications. However, missForest misclassified 1 patient as ‘Caucasian’ and 2 as ‘Black of African American’. Further analysis is suggested such as application of our method to other data sources.

In Table 2, the coefficients of linear regression models, after imputation using MICE, show that all the variables included in the model are significant. Nonetheless, imputed values with missForest imputation show less significance. Gender, treatment and lymphocytes are the most significant with missForest imputation. Figure 1 also shows the distributions of the observed and imputed values for missing variables problem. As we see in figure 1 extreme values affect the shape of the plots. However, the central tendencies of the density plots of imputed data appear relatively similar to the observed ones.

In general, our approach contains a number of important ingredients. First, it insists on the future existence of health data heterogeneity. Therefore, our approach strives for

post alignment rather than pre-alignment of Big-health/bio datasets. Second, as a post-alignment of heterogeneous data sources will be always imperfect and it is not a problem that datasets are not content equivalent, if they estimate the probability that they are. Third, this approach is pragmatic in the sense that always provides an answer- although it might not better when the source datasets do not provide useful information to answer the research question. However, the results of the probabilistic data integration would be the same as those that would result from analysing an integrated dataset.

5. Conclusion

Existing methods for dataset integration rely on mapping to common data models, often resulting in a substantial loss of information that is present in the source datasets. One promising alternative relies on probabilistic methodologies. This paper has illustrated this approach using a real-world example from Lupus cohort studies. Rather than relying on perfectly harmonised data items, our method propagates the uncertainty that results from imperfect harmonisation into the statistical analysis, thus obviating the need for data integration through a common data model.

Ideally, shared data models would be implemented at source, enabling uniform data collection at different sites and studies. But in reality, data standardisation is always imperfect, and our approach embraces this imperfection rather than trying to extinguish it. Future work includes expanding of the general applicability of the method, and comparing results of the proposed integration techniques with gold standard results through statistical simulation studies. Moreover, to demonstrate its utility the developed approach will be applied to real world biomedical and health datasets such as the studies in SLE that were used for our examples.

Problems in FAIRifying Medical Datasets

Matthias LÖBE^{a,1}, Franz MATTHIES^a, Sebastian Stäubert^a, Frank A. Meineke^a, and Alfred WINTER^a

^a*Institute for Medical Informatics, Statistics and Epidemiology (IMISE), Leipzig University, Leipzig, Saxony, Germany*

Abstract. Despite their young age, the FAIR principles are recognised as important guidelines for research data management. Their generic design, however, leaves much room for interpretation in domain-specific application. Based on practical experience in the operation of a data repository, this article addresses problems in FAIR provisioning of medical data for research purposes in the use case of the Leipzig Health Atlas project and shows necessary future developments.

Keywords. FAIR data, Research data management, Data sharing

1. Introduction

The FAIR Guiding Principles for scientific data management have been widely accepted since their publication in 2016 [1]. Nevertheless, their practical implementation is difficult, especially in the area of particularly sensitive personal medical data. While many data repositories and data management solutions claim to be FAIR, the qualitative implementation of the FAIR principles varies [2]. A typical university hospital supports various types of research projects in addition to patient care, such as clinical trials for the approval of new drugs or therapy optimization, disease-specific registries for the most complete possible registration of all patients suffering from a specific disease, population-based cohorts for epidemiological long-term monitoring of the population, biomaterial banks, molecular genetic analysis (OMICS) and much more. Most of these research projects generate high quality data in terms of completeness, consistency and accuracy. Data is collected, curated, analyzed; but rarely used again. The objective of this contribution is to show the problems that arise when building a research data repository in accordance with the FAIR principles, with special emphasis on the health research domain.

2. Method

Medical research on humans is resource-intensive and ethically challenging, so it should be made possible to get the maximum out of the data. The Leipzig Health Atlas is a research data repository that has been built up over the last few years [3] and is now constantly being filled with content. Based on the SEEK platform [4], not only

¹Corresponding Author: Matthias Löbe, Härtelstraße 16-18, 04107 Leipzig, Germany; E-mail: matthias.loebe@imise.uni-leipzig.de

data sets but also other types of research artefacts such as systems biology pipelines, bioinformatics models or medical ontologies will be managed. In addition to the core task of long-term archiving data are to be made available to other researchers ("Data Sharing") and analyses of data should be repeatable by third parties ("Reproducibility"). The method empirical-analytical approach used here is based on our experience in operating the portal and the consulting and feedback of scientists when uploading their results.

3. Results

This chapter outlines various FAIR hurdles for biomedical research, broken down according to the main axes of the FAIR principles, which have arisen several times and for which proposals are made for dismantling them.

3.1. Considerations for FAIR axis 1: Findability

Findability deals with the problem of recognising the existence of resources and referencing them. Many data repository software systems or content management systems assign (locally) unique numbers by themselves, which could be made globally unique by a suitable prefix. However, the required "eternal persistence" cannot be guaranteed with regard to updates or system changes. This results in the need for special digital identifier registry software. Such systems already exist in the medical field, e.g. the HL7 Object Identifier (OID) Registry as defined in the recommendation ITU-T X.660 and ISO/IEC 9834 series. Unfortunately, the OID system [5] is only one of many possible handle systems, Digital Object Identifiers (DOI) are widely used in scientific journals, and Uniform Resource Identifiers (URI) are used in distributed web-based software systems. While each of these systems can be designed to be *resolvable* in principle, there is no agreement on other desirable characteristics [6] such as descriptive human readable designation as part of identifiers.

Another problem is the granularity at which data is to be assigned its own identifiers. It is undoubtedly important, for example, to provide a data set that was the basis of a scientific publication in one version with its own identifier. However, medical databases are characterized by frequent and extensive changes, whereby data is not only added, but also updated. A continuous versioning would be impracticable here. A further problem is that it is desirable with regard to the use of data by external systems to also be able to reference only parts of data sets or single data elements. In the sense of the idea of a Semantic Web, each information atom would get its own URI, which is, however, insufficiently supported in practice by existing software.

While the actual search can be very well supported by existing software using keywords, ontologies, or categorical filters, there is a lack of community accepted metadata vocabularies for describing data sets (such as MIAME – Minimum information about a microarray experiment or the WHO Clinical Trial Registration Data Set) for many areas of biomedical research, which often makes it difficult for users to navigate within a repository. Furthermore, due to the growing number of repositories, it would be desirable if these were federatively linked so that a user does not have to formulate a request several times in different places and aggregate the results. Here, too, there is a lack of a unifying data catalog specification for available

health data describing the content of data collections and the location. Ultimately, individual data elements must be described very precisely in order to prevent misinterpretation. Simple designations cannot do this. Metadata repositories (MDR) allow semantic specification of clinical concepts through annotation with medical terminologies, as well as the precise specification of units of measurement, formats, data types, and reference ranges. Different systems exist, but their use is very complex and does not fit into the regular work processes, which limits their application [7].

3.2. Considerations for FAIR axis 2: Accessibility

Accessibility enables a researcher to actually retrieve data. To have metadata permanent available, even when the data are no longer available, is quite easy to achieve technically but harder to enforce culturally because some researchers have not yet fully embraced the meaning of this criterion. Access via a standardized communication protocol is also not a technical problem since Representational State Transfer (REST) interfaces based on the HTTP protocol have established themselves and current open standards such as HL7 Fast Healthcare Interoperability Resources (FHIR) [8] are based on them. The difficulties with access to personal medical data lie rather in their sensitive nature for the individual patient. Comprehensive regulations such as the European General Data Protection Regulation (GDPR) regulate in detail the conditions and restrictions for their collection and further processing. In general, the use of such data for research purposes requires the informed consent of the patient or proband. The declaration of consent must be sufficiently specific with regard to the research objective, the persons accessing the data and the circumstances of the data processing, which can prevent subsequent data sharing. Also, identifying data must not be stored together with other research data, which makes subsequent data collection or record linkage more difficult. Furthermore, participation in research projects is always voluntary and can be recalled at any time. Anonymisation procedures for individual medical data can remove these restrictions, but are accompanied by a great loss of information entropy. For this reason, it is necessary to create and use further harmonised metadata vocabularies on topics such as the legal basis for data collection or the different variants of Informed Consent.

Since such data will rarely be automatically accessible, the process of requesting data access and secure data retrieval plays an important role. In practice, a simple reference to a contact person for each data record represents a major hurdle for both the data holder and the interested party, since medical researchers are not always fully aware of the legal framework. The establishment of a Data Access Board for checking and approving data use proposals according to a usage concept is strongly recommended. The data repository should provide an authentication service for internal and external users based on a rights and roles concept. To address the concerns of data owners about possible breaches of data privacy during data sharing, contact points for questions regarding data sharing, data protection, etc. should be established.

Further problems regarding permanent accessibility are contradictory rules for the storage of data. While individual funders consider a storage period of at least 10 years as part of good scientific practice to be appropriate, some data usage agreements state that the shared data must be deleted immediately after the end of the project, which has already led to data records no longer being available shortly after the publication of a scientific article. A regulatory harmonisation must take place here.

3.3. Considerations for FAIR axis 3: Interoperability

Interoperability is the ability of distributed, heterogeneous systems to exchange information in an unambiguous and exploitable manner. There are countless standards, conventions and best practices in biomedical research, but in many cases researchers take advantage of the freedom of science to act according to their own ideas. For the operators of research data repositories, this often means that only minimal ideas about data structures can be enforced (e.g. a tabular format with character-separated values).

Since technical and semantic interoperability are generally subject to higher requirements, operators should support data owners in transforming the data into a widely applicable format for knowledge representation. Such a FAIRification process requires the definition of a rich target data model. Various common data models are suitable for this; the selection can be influenced by later intentions of use. The latest, but also most universally applicable model is the already mentioned HL7 FHIR. It covers practically all areas of medicine, even if some resources are not yet finally specified. In the area of clinical trials, the standards of the CDISC organization are of importance, especially the Operational Data Model (ODM) [9] in conjunction with the Study Data Tabulation Model (SDTM). For large, distributed data analyses, the OHDSI Observational Medical Outcomes Partnership (OMOP) [10] model has gained great popularity. For all these models, however, rudimentary ETL tools are available at best.

International medical terminologies such as ICD-10, LOINC or SNOMED CT are very suitable for describing clinical concepts in detail. They only partially meet the requirement that vocabularies should also comply with FAIR principles. Terminology services can aid the linking process.

3.4. Considerations for FAIR axis 4: Reusability

Reusability describes the application of data for secondary purposes independent of the original use. With regards to medical data, provenance is the most important topic of the FAIR reusability metric. While provenance is a broad topic and the demarcation to data acquisition is not sharp, data owners should specify in detail the circumstances of the data collection and processing, i.e. data sources, data validation rules, format conversions, data cleansing, derived or aggregated data, measuring instruments, scripts, software libraries, observers. This greatly increases the confidence of external researchers in the data sets. A further recommendation is the provision of simple web-based visual analysis tools such as tranSMART [11], which give potential interested parties an overview of the depth of the available data and so enhances reusability.

3.5. Additional considerations for medical FAIR data

Some aspect does not fit into one of the FAIR data categories but are nevertheless part of our recommendations: 1) Data quality is a primary concern when one relies on external data. All procedures to ensure high data quality (technical validations, manual curation) should be made explicit. 2) If datasets are not eligible for sharing (privacy, volume), privacy-preserving data analysis techniques could be an option. 3) Repository operators should provide additional services to facilitate sharing and usage of data e.g. pseudonymization, de-identification, anonymization, record linkage. 4) The effort and benefit of FAIR verification of data is generally unevenly distributed at the expense of

the data owner. However, an incentive for them may be to receive feedback on improved or additionally calculated data and to add it to the original data source.

4. Discussion and conclusion

The FAIR data principles can well be applied to medical data repositories, yet some restrictions will apply, mostly with regard to accessibility/data privacy. The LHA project is work in progress; not all of our recommendations are solved, implemented and evaluated yet. Even through some of our findings lack a broad, independent evaluation, we expect most of them to be translatable to similar projects. A first draft of a guideline for implementing a general FAIR open data policy in health research was developed as part of the FAIR4Health project [12].

The greatest difficulties for FAIRification currently lie in the lack of availability of community-consented vocabularies and powerful tools for transforming data to common data models like HL7 FHIR. While several initiatives (e.g. FORCE11, GOFAIR, Research Data Alliance) assess the coverage of the FAIR principles of different systems and publish FAIR metrics onto how these principles should be put into practice, effort and costs are currently too high for many common data collection projects. Incentives are needed to take on the challenge of FAIRification. Furthermore, there should be more standardization on processes for data access and data extraction.

Abstract. Next generation sequencing (NGS) technologies allow improved understanding of pathogens. In the upstream processing of generating genomic data, there is still a lack of process-oriented tools for managing corresponding meta data. In this paper, we provide a description of how a process-oriented software prototype was developed that allowed the capture and collation of metadata involved when doing NGS. Our question was: How to develop an interactive web application that supports the process-oriented management of genetic data independent of any sequencing technique?

Keywords. data management; microbiological data; ngs; web application

1. Introduction

Modern microbiological laboratories use next generation sequencing (NGS) for understanding the genomes of pathogens. This allows, for example, the detection of outbreaks and the determination of antibiotic resistance mechanisms. In order to generate annotated genomic data, bioinformatic and biomedical knowledge are necessary. For NGS analysis, software solutions such as Ridom Seqsphere+ [1], CLC Genomics Workbench [2] or UGENE [3] can be used and facilitate the analysis of sequence data, annotation, alignments, and visualization such as phylogenetic trees. However, there is more information involved in the upstream processing of generating genomic data, which are often not fully considered in such approaches [4].

The collection and reliable storage of metadata relating to the sample is critical, particularly in an ISO accredited clinical microbiology laboratory, but also of relevance to other laboratories performing NGS. Three steps for generating a genome-based laboratory typing report from a clinical sample can be distinguished: sample preparation, sequencing and analysis. In the sample preparation step, clinical samples or isolates are subject to DNA extraction. In this stage, relevant data relating to the patient, the sample, and the extraction are collected. In the sequencing step, data on the concentration of DNA, the library method, the sequencing platform used, and a quality

¹ Corresponding Author, Murat Sariyar, Bern University of Applied Sciences, Quellgasse 21, CH2502 Biel/Bienne, Switzerland; E-mail: murat.sariyar@bfh.ch.

control of the resulting sequences are annotated. In the analysis step, the sequences are interpreted, for which biomedical information is indispensable.

The workflow of capturing and collating metadata during NGS was analyzed in the Division of Bacteriology at the University Hospital Basel. The processes for capturing the data associated with NGS were examined before starting the process of software development. At baseline, Excel worksheets on a server were used with no established workflow of how and when to commit changes or new entries. Our central goals were to facilitate NGS metadata management in order to reduce the likelihood of errors in the database and allow for parallel editing of different parts of the database. The guiding research questions was: How to develop an interactive web application that allows an efficient process-oriented management of genetic data independent of any sequencing technique?

2. Methods

With a Pubmed and Google Scholar research using the keywords “metadata microbiology”, “ngs metadata”, “pathogen ngs metadata”, “metadata management system” and “metadata management system genome” we checked if an external tool for our goals is available. Next, we iteratively created a mockup together with the laboratory staff using the Figma mockup tool [5] in order to define an optimal workflow. The subsequent requirement engineering process was based on IEEE 830-1998 [6] and lead to the definition of the software architecture.

In the development phase, we used the agile SCRUM technique [7] with seven sprints lasting one week each. We made use of the JavaScript node.js (loopback) framework for the backend and the Vue.js framework for the frontend. The REST-based philosophy of many JavaScript frameworks is not designed for multiuser systems that require isolated updates and deletion of common resources. Therefore, we used *socket.io* as a JavaScript library for real-time web applications that enables bi-directional communication between web clients and servers, ensuring that locks on datasets can be propagated beyond one session within a REST-based access [8]. For usability tests based on a structured questionnaire and for final modifications according to the answers, two more weeks were scheduled.

3. Results

In our analysis of the management of genetic meta data, we identified six central process steps concerning the weekly sample preparation workflow. Initially, a laboratory order from internal or external customers arrives together with the material to be sequenced. The order is validated and prioritized. In step 2, the sample type (isolate or DNA) is checked. Step 3 selects the necessary DNA extraction process with respect to the material, if required. Step 4 selects the number of samples (4, 24, 48, or 96 depending on the sequencing device and cartridge). After performing the DNA extraction, the sequencing can be planned with the information generated during extraction (step 5). Finally, the samples for the next NGS run are selected, a sequencing run is performed, and sequencing data is saved for later analysis and reporting (step 6).

These process steps are divided into four different views according to the data input required. For steps 1-2, it is the view “*Planned*” with data on the requesting facility, the patient, the type of the material, the date of receiving the order, the type of the pathogen, the priority of the order (from “A”: high to “D”: low); the view for step 3 is “*extracted*” with the same data as in the former view and DNA concentration; the view for steps 4 and 5 is “*Preparing run*” with data on the finalized DNA extracts to be sequenced; for the last step the view is “*Sequenced*” with data on the sequencing device used, date of sequencing and some of the sequencing properties, e.g. adaptor oligonucleotides ligated to fragments of the DNA for forming the DNA library.

During the requirements analysis, we also identified the original data management workflow based on Excel worksheets, which showed several disadvantages:

- Lack of information on the order of inserting data into the Excel worksheets
- No import options for pre- formulated orders, potentially leading to errors in manual entries
- No export options for selected data, which could lead to errors in manual copy/paste operations during report generation
- No support for batch processing of the data
- No possibility of representing a complete repetition of a sequence run by shifting metadata from the view “*sequenced*” to former views

To implement a web application that addresses these disadvantages and provides an affirmative answer to our research questions (see introduction), we considered additional functional and non-functional requirements, e.g. a table view for general overview or ubiquitous access to the system from everywhere within the laboratory, which mandates a web interface that is compatible with current browsers. The main non-functional requirement was user guidance through the metadata management process by prompting only for relevant fields in each step and by providing help functions, sorting options, search functions as well as tooltips. The prototype is called “Red Maple”, and the start page is given in Figure 1. The UML sequence diagram for our solution using web sockets is presented in Figure 2.

Figure 1. Start page of the prototype *Red Maple* with the four views “Planned”, “Extracted”, “Run”, “Sequenced” and a summary of datasets included in them. The bubbles in the right column represent the links for details within these views.

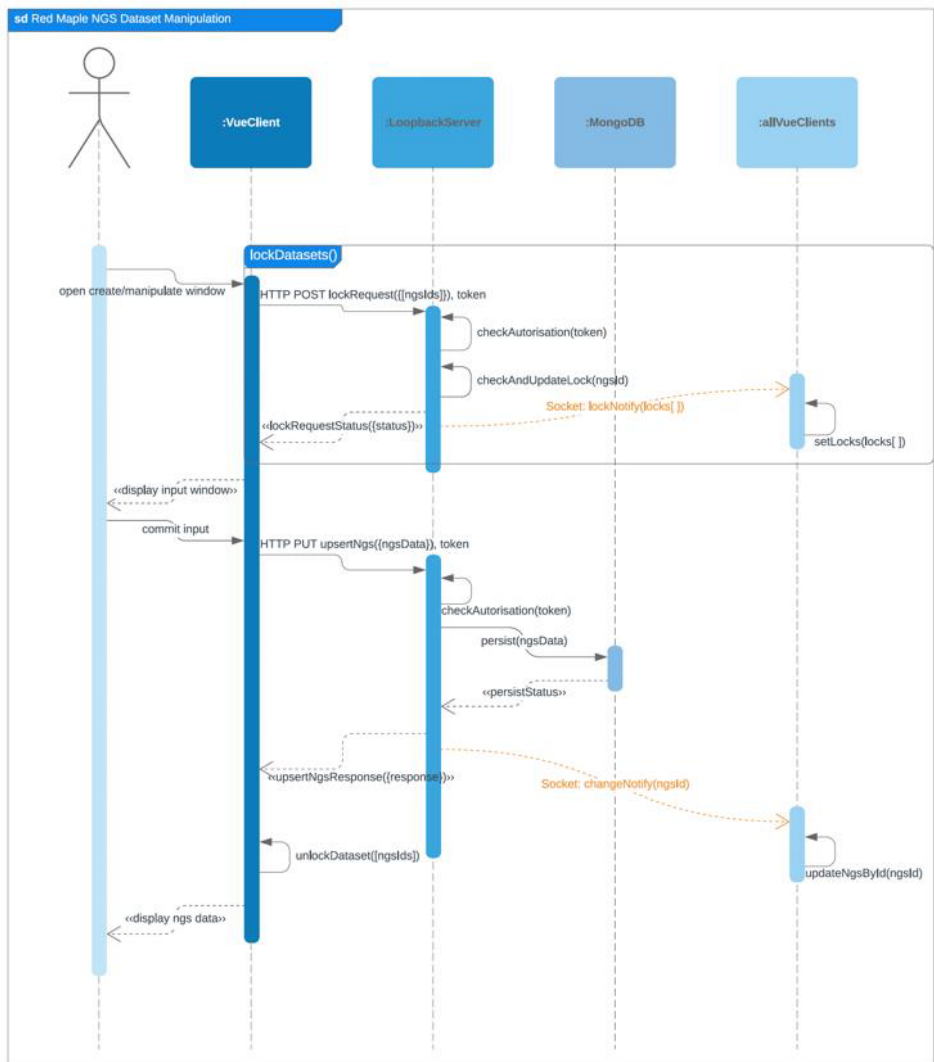

Figure 2. The UML sequence diagram shows how data is accessed via the frontend (VueClient). In case of manipulation of the data, tokens are used, which allow manipulation of data in the backend (MongoDB is the NoSQL database used by the loopback Server). Locks are necessary in order prevent anomalies possible when the same data is tried to be manipulated simultaneously.

4. Discussion

Typically, laboratory analyses are associated with clear diagnostic procedure steps described in medical guidelines. The NGS processes within microbiological laboratories are different in that they are often not directly based on a medical guideline but are necessary to gain information on transmission and outbreaks, thus affecting

more than one single patient. This is one of the reasons why such NGS analysis processes are difficult to integrate into the workflow of existing laboratory information systems. Hence, instead of stretching existing LIS solutions, it seems desirable to develop a modular solution that is useful for many microbiological laboratories. Therefore, we implemented and described an exemplary web application that supports an efficient process-oriented management of NGS-related meta data.

One important advantage of our REST-based prototype is the increasing number of RESTful applications and clients that can be easily interfaced in future, for example the biobank software *OpenSpecimen* [9]. HL7 FHIR is an important standard for RESTful medical software applications that makes RESTful service-oriented architectures increasingly attractive for the data management of a variety of “non-standard” clinical data.

Due to project time constraints, there are some limitations. Today, the prototype is not yet in routine use. We collected positive reactions from future users and measured decreased processing time, but no systematic study of the effects of the new solution has been conducted. Future work will also concentrate upon more sophisticated statistical reports for the data.

Providing an Integrated Access to EHR Using *Electronic Health Records* Aggregators

Belen PRADOS-SUAREZ^{a,1}, Carlos MOLINA^b and Carmen PEÑA-YAÑEZ^c

^aUniversity of Granada, Granada, Spain

^bUniversity of Jaen, Jaen, Spain

^cSan Cecilio Hospital, Granada, Spain

Abstract. The integration of health data systems is an open problem. Most of the active initiatives are based on the use of standards, each one proposed for a concrete use, without integrating other needs or standards allowing on homogenous use. We propose an alternative to get an unified view of health related data, valid for several uses, that can integrate heterogeneous sources. The proposal set the framework to integrate the developments made so far to automatically learn the extraction and conversion of the data. All the sources are integrated under a single access point. We present the main concepts of *EHR_{agg}* as a middleware between systems that can incorporate several sources giving an unified access following the FAIR principles.

Keywords. Health Data, Interoperability, Data Mining, Natural Language Processing

1. Introduction

Nowadays the need for interoperability between Hospital Information Systems is obvious, as it enables patient mobility, not only geographically, but also between medical services and health care providers.

Many efforts have been made to achieve this *interoperability*, starting with standardization initiatives (e.g. [9,10]). The main issues with these standards are two: first, there is no agreement about which one to choose; and second, it is going to take long before all the systems comply with these standards and become effectively interoperable, due to the huge efforts required to adapt current ad hoc hospital information systems.

This is a problem that also affects data *accessibility*, especially in health research, where data science offers very promising and useful tools ([1,2,3]), but has limited data to work with. This is due to the lack of integrated and standardized datasets for health data. Many initiatives to improve the quality and number of sources for research have been proposed (e.g [4,5,6]). For example, both USA ([7]) and Europe ([5]), have developed catalogues where researchers can add references to datasets and look for others, but

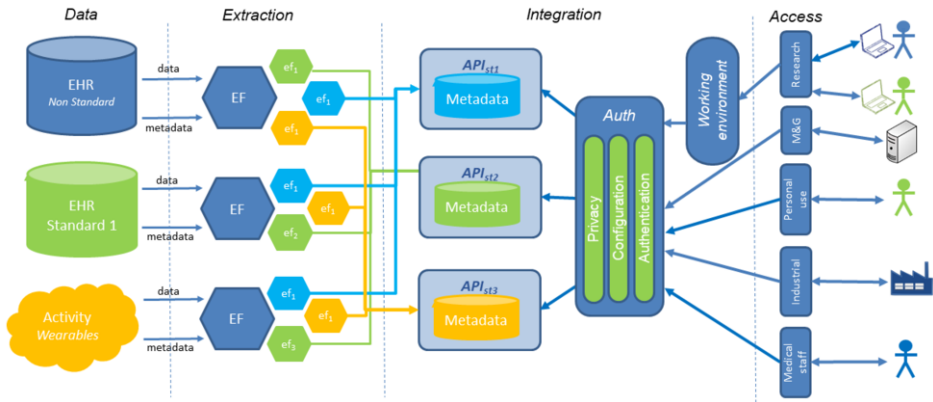

Figure 1. Architecture for EHR_{agg} systems

they need to adapt the data or methods to work with each of the datasets. As Schulz et al. indicate ([8]), although several standards have been developed, they are not generic enough to be valid for different uses.

Moreover, there is a third variable to add to the current landscape. New personal devices are emerging every day, which gather very useful information about people's way of life, but they are developed by private companies under different ad-hoc implementations, and completely disconnected from the rest of the systems and datasets.

In sum, we are faced with the following circumstances: (1) several sources of information, not only from medical institutions, that should be integrated; (2) different access needs with distinct requirements (personal use, medical use, research purposes,...), especially regarding privacy protection; and (3) the need for a homogeneous access point for all this data, with adaptation capabilities (to fit new systems, standards and needs), but without the need to transfer the ownership of the data.

The main idea is to build what we call an *EHR Aggregator* (EHR_{agg}) that integrates the developments made so far (and upcoming ones) to automatically learn how to convert current information systems into standard systems. This system also includes a layer that operates as a homogeneous access point to the information stored in all the sources, without necessarily having to transfer the data, but enabling its processing.

Here we present the concept of EHR Aggregator and the conditions that each element should comply with in section 2. Our purpose here is to present the general structure. In section 3 we put forward our conclusions about how it aims to solve these issues.

2. General Structure

In this section we cover the concept of Electronic Health Record Aggregator. We first present the idea and the general structure, while the following subsections are dedicated to describing each of the elements in the structure.

An *EHR aggregator* (EHR_{agg}), in Figure 1, is a system that acts as middleware between EHR systems and others with health-related data (e.g. activity, sleep analytics, etc.) and the users that want to access the information (which can be people or other systems). It provides a unified view of the underlying Health Data Systems, in the *Data*

Layer, by learning automatically, and in the *Extraction Layer*, by converting the information stored within. This uniform access point allows the user to query and retrieve information from all of the systems without adapting the access to the architecture of each one, which is possible through the *Integration Layer*. This layer acts as a unique access point to all the collected data for external applications. To improve reusability, there are platforms in this *Access Layer* that collect and update the generic functions to facilitate the implementation of external applications. Each of these layers are discussed in the following sections.

2.1. Data Layer (DL)

One of the main elements of the structure are the sources of information. From each one we have to obtain not only the data, but also the metadata. We then need to convert or translate this information in order to integrate it into the aggregator.

Depending on the type of data, we can use different functions to perform this conversion. For example, the functions to convert metadata may be different from those to convert data, and those used for images may be different from those used for medical analysis information. Each of these functions are called *extraction function* (*ef*).

During this process it is essential to consider the quality of the conversion. In a perfect situation, we will translate the information without any loss of data or metadata. In this case we will consider a value $c_i^j = 1$, indicating a perfect conversion. However, in most of cases we will not have perfect conversions, so we shall indicate this using a value in the $[0, 1]$ range. The nearer to 1 the value, the better the conversion is, and the less information is lost.

2.2. Extraction Layer (EL)

The most critical part is to retrieve the data from the source systems and transform it so that the API (application programming interface, see next section) can access all the information. The components in charge of this, called *ef* (extraction functions), transform the information stored in the source systems, to allow the API to work with it.

If the source is based on a health standard (e.g. [9,10]), the conversion may be direct but not always is so ([8]). Most of the current health data systems are not completely based on standards, so we need to adapt the data. So far, great advances have been achieved in standards compliance. However, system standardization, in most situations, is very complicated or, under the best circumstances, is costly in time and effort. This is why we propose here to get the most of these advances by using methods that automatically learn how to perform the conversion from any system to one of the standards and between the standards themselves.

This automatic learning process allows us to (1) directly integrate systems that already comply with one standard; (2) reuse the learned transformations to apply them in the integration of other non-standard compliance systems, and (3) keep open to future standards, sources or advances in integration or interoperability.

Depending on the type of data, we may define different *ef* functions. For non-standard systems, the *ef* need to learn the structure of the data (and metadata) and transform it to be used by the *EHR_{agg}*. Most EHR systems are based on semi-structured documents and we can find several proposals in the literature using Text Mining to extract

data from EHR (see [11]). Other approaches are based on Natural Language Processing (NLP) ([12,13,14]). These processes can be applied to extract not only data but also metadata. In both cases, the proposed solutions can be tested to obtain information regarding confidence in the conversion, and the best algorithm for each concrete type of data will be chosen. This value, normally in $[0, 1]$, provides the user with information regarding the confidence of the data offered by the aggregator. We can define the *ef* function combining several proposals according to the data to be transformed.

2.3. Integration Layer (IL)

The *IL* has three components. First, the *API* itself, with the methods to access and/or retrieve the data from *EL* and providing access to the functions and the working environment. The *authentication* module, which controls and registers the accesses, configures privacy restrictions, and ensures compliance with regulations. The last one is the *working environment*, where the access platforms can process all the data without having to leave the system, and avoiding the transfer of the data to other layers.

Through the *API*, the user has access to the information stored in each and all of the data sources integrated in the *EHR_{agg}*. It maximizes accessibility to information, with the only restrictions being those imposed by regulations and privacy protection rules. Using this *API* to develop their applications, users can run queries over all the data and metadata available in a homogeneous way, regardless of where it comes from or how it is stored. It is possible because the *API* makes use of the extraction functions to retrieve the data.

The second element is the *Authentication* module. It has the following functions: To register all of the data retrievals, regardless of the *API* used (*authentication module* in *Auth* block (*AB*)); to control privacy protection restrictions imposed by the source that provides the data or according to how the data will be used (*privacy* in *AB*); to adapt the access point to different regulatory frameworks (*regulation configuration* in *AB*).

Finally, we have the *working module*, that enables direct processing of data without really having the data. The idea is to offer a work space where, for example, researchers can use the *API* to launch their methods and perform calculations on the data, without retrieving the data or transferring it from the source institution.

2.4. Access Functions (AF)

The access layer is used to run queries in the system. Since we are referring to a large-scale system, we have taken into account that there will be different access requirements, depending on how it will be used. For example, research activities may require anonymized data and statistical methods, while a medical EHR system needs access to detailed information of the EHR of a concrete patient homogeneously, when the data in the original sources is spread out and fragmented. Therefore, as a starting point, we have identified at least five types of data use with distinct needs. These are: personal use of data, medical use, use for research, for management and governance purposes, and industrial use. This is not a closed classification, since new needs may arise in the future.

Here we propose to build an *access platform* per use or purpose where, in a similar way to software as a service (SaaS) platforms, the most frequent operations will be implemented for each given use. This way, as shown in figure 1, they can be reused by *external functions*, applications and systems of users with similar needs.

Finally, *external functions* can only access the system through the *access platforms*, which in turn have access from the *working module* or directly through the *API*. Let us remark that in any case, all of the access points pass through the *authentication module*.

3. Conclusions

With the EHR_{agg} we propose to address the interoperability and accessibility problem using the same pragmatic approach: instead of trying to have all the systems agree with the same standard, we propose a translation between standards, and of systems to any standard, reducing effort and time. It includes an integration layer that acts as a single access point, offering an unified view of the underlying data sources. This layer also ensures access control, privacy protection and adaptation and compliance with regulations. In addition, it has an access layer especially designed to facilitate the development of external access functions, based on the principle of reusability.

It is an ambitious proposal that aims to centralize current efforts to accelerate understanding between health-related systems. Here we present the general structure of the *EHR aggregator*, establishing the first steps to build a unified framework, but there is still a lot of work to be done. Some of the current and future lines of work focus on the study of access time requirements, feedback on the *ef* used to improve the system, the classification of access functions and their assessment to be integrated in the access platforms. Nevertheless, we believe this practical and open approach can give great results in the short and medium term.

Abstract. The geographical imbalance of the healthcare workforce is a social problem in Japan. Except for big cities, hospitals have difficulties in securing a sufficient workforce to offer healthcare services stably. For local government, hospital service suspensions are potentially an essential indicator to figure out the capacity of the regional healthcare supply. This paper proposes an algorithm that automatically identifies and classifies hospital service suspensions from insurance claims data, based on periodicity and similarity. To verify the effectiveness, we have applied the algorithm to the insurance claim dataset, which has been provided 91 regional public insurers in Japan. The case studies have confirmed that the proposed algorithm has presented an evidential picture of hospital service suspensions, which is potentially useful to understand the actual capacity of healthcare service supply in regions.

Keywords. Hospital service suspension, insurance claims data

1. Introduction

The geographical imbalance of the healthcare workforce is a common problem in many countries. Japan is no exception [1-2]. To tackle this problem, the Ministry of Health, Labor and Welfare of Japan has been executing several healthcare policies from 2008 [3]. As a result, the number of health workforce (especially physicians) has been increasing. However, a recent study showed that the supply capacity of the health workforce was still imbalanced between urban and rural areas in Japan [4]. In addition, this study showed that the supply capacity of the health workforce was decreasing in rural areas. Except for limited big cities, hospitals have difficulties in securing a sufficient workforce to offer healthcare services stably. Hence, understanding the balance supply capacity and healthcare demands is crucial for local governments to design their healthcare policies effectively.

To figure out the capacity of the regional healthcare supply, hospital service suspensions are potentially an essential indicator for local governments. In this paper, we present our idea of identifying hospital service suspensions from healthcare insurance claims data. Japan has established the universal health insurance system since 1961 [5];

¹ Corresponding Author, Jumpei Sato, Institute of Industrial Science, The University of Tokyo, 4-6-1 Komaba, Meguro-Ku, Tokyo, Japan; E-mail: jsato@tkl.iis.u-tokyo.ac.jp

all the medical services are covered by the public healthcare insurance programs. The healthcare insurance claims have the great potential to reveal the hospital service suspensions thoroughly and precisely.

In this study, we propose an algorithm that automatically detects and classifies the hospital service suspensions from a large amount of insurance claims data, based on periodicity and specificity and present case studies to demonstrate the effectiveness of the algorithm. The remainder of the paper is organized as follows. Section 2 describes the proposed algorithm, Section 3 presents case studies using four and half years of insurance claims dataset, and finally, Section 4 presents conclusions and discussions.

2. Method

The algorithm proposed in this paper detects and classifies hospital service suspensions from healthcare insurance claims data. The algorithm can be roughly divided into the following two steps: Step1; scans the given healthcare insurance claims data and then identifies services suspensions of each hospital based on the daily occurrence of medical services, and Step2; classifies service suspensions based on the periodicity and the similarity of suspension occurrences and the heuristic rules. The following two sections describe these steps in detail.

2.1. Identify hospital service suspension from the healthcare insurance claims data

Healthcare insurance claims data (standardized in Japan) does not directly contain the information of hospital service suspension. Instead, the claims data contain detailed information of medical service provision from hospitals to patients. That is, each claim records a date, a hospital identifier, a patient identifier and one or more medical service codes. Firstly, the algorithm aggregates a large amount of healthcare insurance claims to predict off (non-consultation) days of each hospital. Specifically speaking, the algorithm calculates, from the insurance claims, a service provision function for each hospital, $y(t)$, which denotes the number of patients that the hospital consulted on a date t . Obviously, the date tt satisfying $y(t) = 0$ is highly likely to be an off day for the hospital. Our algorithm thoroughly scans the healthcare insurance claims to list all the off days for each hospital; if four and more consecutive days are off for a concerned hospital, these off days are recognized as a service suspension².

2.2. Classify hospital service suspensions

The proposed algorithm classifies the hospital service suspensions into the following four types based on the periodicity and the similarity of suspension occurrences and the heuristic rules: (a) apparent service suspensions before hospital open, (b) apparent service suspensions after hospital close, (c) anormal service suspensions, and (d) regular service suspensions (planned, including weekends and holidays).

First, by the heuristic rules, the algorithm classifies the suspensions into the before hospital open or the after hospital close. If the duration of the suspension is over a month

² In Japan, many organizations including hospitals are off on Saturday and Sunday, and national holidays are often placed on Monday. After intensive exploration, we came to define four and more consecutive off days as a suspension to distinguish such weekend off days.

and started from the first data of given claims data, the algorithm classifies the suspension as the before hospital open. Likewise, if the duration of the suspension is over a month and ended on the last date of the given claims data, the algorithm classifies the suspension as the after hospital close.

Next, based on the periodicity and the similarity of suspension occurrences, the algorithm classifies the remaining suspensions into the anormal or regular service suspensions. Generally, scheduled hospital suspensions would occur at regular intervals (weekly, annually)². Therefore, the algorithm calculates the periodicity $pw(t)$ by using the trends and cycles model [7] as follows:

$$y(t) = g(t) + s(t) + \varepsilon_t, \quad pw(t) = \begin{cases} y_{fitted}(t), & (t \mid y(t) = 0) \\ 0, & (t \mid y(t) \neq 0) \end{cases} \quad (1)$$

Where $y(t)$ is the time-series data calculated in Step1, $g(t)$ denotes a constant up/down trend, and $s(t)$ denotes the weekly/annually periodic changes. ε_t denotes error terms. $y_{fitted}(t)$ represents a fitting result of the trends and cycles model.

Furthermore, in Japan, many hospitals schedule their day off around August 14 (called the “Obon” holidays), despite not national holidays. Such as the “Obon” holidays, the suspensions when many hospitals were suspended similarly can be considered as scheduled suspension. Hence, the algorithm calculates the similarity $sw(t)$ referring to the idf (inversed document frequency) index, which can measure whether a suspension is similar (common) or rare:

$$sw(t) = \begin{cases} \log_2 \left(\frac{\# \text{ of suspended hospitals on each date: } t}{\# \text{ of total hospitals}} \right), & (t \mid y(t) = 0) \\ 0, & (t \mid y(t) \neq 0) \end{cases} \quad (2)$$

Our algorithm classifies the remaining suspension, which contains the four and more consecutive days that satisfy $pw(t) + sw(t) > 16$, as the anormal service suspension. Finally, the algorithm classifies the remaining suspension as the regular service suspension.

3. Result

In our study, we used the insurance claims dataset of 91 regional public insurance providers in the Mie prefectural area in Japan. This dataset contained 71.53 million claims (1.676 billion records) from March 2013 to November 2017.

3.1. Case study1: detecting and classifying service suspensions

First, we applied the proposed algorithm to the dataset. Figure 1 shows an example of the visualization result of the suspended dates for each hospital. In Figure 1, the horizontal axis represents date t , the vertical axis represents each hospital, and each column shows the number of patients who provided medical services on each date. The no service provided dates are shown in colored. As shown in Figure 1, in many hospitals, the no service provided dates appeared at a cycle of a week. In addition, early May, which

has many national holidays, “Obon” holidays and New Year’s holidays showed that many hospitals were suspended at the same time.

Table 1 shows the details of the number of suspends detected and classified by the algorithm. The algorithm identified 12,813 service suspensions in total, which were classified into (a) 12,217 regular service suspensions, (b) 523 anormal service suspensions, (c) 26 hospital opens, and (d) 47 hospital closes. The number of service suspensions the highest in the urban areas (populations are $\geq 100K$), second in the medium areas (populations are $<100K$ and $\geq 10K$), third in the rural areas (populations are $<10K$) for each suspension type.

Figure 1. Example of the visualization of the suspended days (the no service provided dates are colored).

Table 1. Details of the number of suspend detected and classified by the algorithm.

	Regular service suspension	Anormal service suspension	Hospital open	Hospital close
Urban areas	8,741	428	20	32
Medium areas	3,358	89	6	13
Rural areas	118	6	0	2
Total	12,217	523	26	47

Figure 2 shows the average duration of the regular and anormal service suspensions. The average duration of the regular service suspensions was 5.37 days in the urban areas, being significantly longer than that of the medium areas (5.21 days ($p<0.01$)) and the rural areas. (4.81 days ($p<0.05$)). On the other hand, there was no significant difference in anormal service suspensions (the urban areas: 8.51 days, the medium areas: 10.04 days, the rural areas: 8.17 days). Figure 3 shows the average frequency of the regular and anormal service suspensions. The average frequency of the regular service suspensions was 5.90 times in the rural areas, being significantly lower than that of the urban areas (11.52 times ($p<0.01$)) and the medium areas (11.82 times ($p<0.05$)). On the other hand, there was no significant difference in anormal service suspensions (the urban areas: 2.30 times, the medium areas: 1.93 times, the rural areas: 2.00 times).

Figure 2. The average duration of the service suspensions (*: $p<0.05$, **: $p<0.01$).

Figure 3. The average frequency of the service suspensions (*: $p<0.05$, **: $p<0.01$).

These results show that regular service suspensions tend to shorter and fewer in rural areas. This trend indicates that the number of hospitals in rural areas is limited, and there are no alternative hospitals in their regions.

3.2. Case study2: the relationship between the service suspensions and the demand behavior

Next, we analyzed the relationship between the service suspensions and the demand behavior of patients. In the dataset, 55 hospitals provided consecutive dialysis treatment to 5,450 patients. In these hospitals, regular and anormal service suspension did not occur. From this result, we confirmed that a stable supply system was established in the hospitals that provided continuous dialysis. On the other hand, 144 hospitals provided consecutive rehabilitation treatment to 29,513 patients. Of these, anormal service suspension occurred in 12 hospitals. 412 patients affected by the service suspensions, of which 406 patients were not receiving rehabilitation during the suspensions and 6 patients were receiving rehabilitation from other hospitals.

This result shows that the anormal service suspensions could occur even in the hospitals that provide consecutive treatments, excepting the hospitals that provide treatments, which have a high impact on life support such as the dialysis.

4. Discussion and Conclusion

In this study, we have proposed an algorithm for detecting and classifying hospital service suspensions from healthcare insurance claims data, and then presented the case studies, which confirm that the algorithm has effectively presented an evidential picture of hospital service suspensions. The present study has been performed with the dataset provided by 91 regional public insurers in Japan. We would like to extend the study to other regions including metropolitan areas.

The next possible challenge is to reveal the resilience of the regional healthcare system, such as how neighboring hospitals compensate suspended healthcare services.

Abstract. In this paper, we propose a new approach for performing privacy-preserving genome-wide association study (GWAS) in cloud environments. This method allows a Genomic Research Unit (GRU) who possesses genetic variants of diseased individuals (cases) to compare his/her data against genetic variants of healthy individuals (controls) from a Genomic Research Center (GRC). The originality of this work stands on a secure version of the collapsing method based on the logistic regression model considering that all data of GRU are stored into the cloud. To do so, we take advantage of fully homomorphic encryption and of secure multiparty computation. Experiment results carried out on real genetic data using the BGV cryptosystem indicate that the proposed scheme provides the same results as the ones achieved on clear data.

Keywords. GWAS, security, homomorphic encryption, cloud computing

1. Introduction

Nowadays, a large amount of genetic data is available enabling the better understanding of the human genome, especially by means of genome-wide association studies (GWAS). The main objective of GWAS is to identify genetic variants associated with some diseases. These studies are mainly based on the statistical analysis of genomic data shared between a genomic research unit (GRU) who possesses genetic variants of affected individuals (cases) and a genomic research center (GRC) who has genetic variants of unaffected individuals (controls). Today, GWAS aims at taking advantage of cloud computing which allows data owners to store and process large amount of data. However, genetic data externalization raises up many questions in terms of data privacy and confidentiality. Indeed, with outsourcing an owner loses the control over his data. Even if a service level agreement has been signed with the cloud service provider (CSP), the user has actually no other choice than trusting him. In addition, the human genome is a very sensitive. It is unique to its owner and can give information about his or her relatives, from a clinical and behavioral point of view. Thus, there is a need for protecting genetic data during their storage or processing in the cloud. In this work, we are interested in securing the

¹Corresponding Author: Gouenou Coatrieux, IMT Atlantique, Inserm, UMR 1101 Latim, 29238 Brest Cedex, France; E-mail: gouenou.coatrieux@imt-atlantique.fr.

collapsing method [1], a case-control study GWAS, with as objective to test whether the proportions of individuals with rare variants in case sample and control sample differ.

Several solutions have been proposed so as to perform privacy-preserving GWAS. The first ones were based on data anonymization techniques such as k -anonymity, but have been shown vulnerable to many attacks [2]. Methods based on differential privacy (DP) [3] overcome these issues. DP adds a random noise to real data so as to ensure individuals' privacy but at the same time reduces data usability. Homomorphic encryption (HE) and secure multiparty computation (SMC) are also used. HE makes possible performing linear operations on encrypted data without decrypting them with the guarantee that the decrypted result equals to the one computed on clear data [4]. SMC allows several parties to jointly compute a function over their data while keeping them private [5]. There exist several approaches based on secret sharing, oblivious transfer and HE [6]. Many HE and SMC based methods have been proposed to secure GWAS statistical algorithms used such as χ^2 -statistic without compromising data usability [5,7,8]. In this paper, we present the first scheme that allows the secure computation of collapsing method based on the logistic regression model. It takes advantage of fully homomorphic encryption, and especially of the BGV cryptosystem which allows encrypting and process blocks of data, in combination with SMC. Contrarily to the previous schemes, it considers that all user data are outsourced and only returns to the users whether the test is significant or not making our solution more secure.

The rest of this paper is as follows. Section 2 comes back on some cryptographic preliminaries and on the collapsing method. Section 3 presents our secure collapsing method. Experimental results and conclusion are given in Section 4 and 5, respectively.

2. Cryptographic and Collapsing method preliminaries

2.1. Homomorphic encryption and secure multiparty computation

Homomorphic encryption (HE) allows performing linear operations (e.g., "+", "×") over encrypted data. Formerly, if E and D denote the encryption and decryption functions, and K_p and K_s are the public and the secret keys respectively, then the homomorphic property states: $D(E(m_1, K_p) \star E(m_2, K_p), K_s) = m_1 \circ m_2$ where: \star and \circ are two operators in the encrypted and the clear/decrypted domains; m_1 and m_2 are two plain-texts. There are three types of HE cryptosystems: partially HE cryptosystems (allow computing additions or multiplications unlimitedly); somewhat HE cryptosystems (allow a limited number of additions and multiplications); and, fully HE cryptosystems (allow unlimited number of additions and multiplications). In this work, we opted for BGV [9], a fully HE cryptosystem because of its homomorphic and batching properties. Batching consists in encrypting multiple messages in one with the capacity to process each message. These properties are of importance in our scheme.

2.2. Collapsing method

This method involves collapsing genotypes across variants in a specific gene and applying a statistical test such as logistic regression. It is a powerful tool for analyzing rare variants. Let us consider a sample of N individuals constituted of N_1 cases and N_2 con-

trols. Let Y_j be the disease status: Y_j equal 1 if an individual j is a "case" or 0 if he/she is a "control". To perform the test, k sites of the studied gene where the variants of interest exist are chosen by GRC and GRU. After this selection, a variable X_i is defined for each individual. It equals to 1 if the individual i has at least one variant allele on any of the k sites or 0 otherwise. The detection of the association consists in testing if the proportion of individuals in cases and controls differ. To do so, a logistic regression model [10] can be used where the outcomes are $\{Y_j\}_{j=1\dots N}$ and the predictors are the variables $\{X_j\}_{j=1\dots N}$. The simplified logistic regression model is defined as $\text{logit}(p) = \ln(\frac{p}{1-p}) = \beta_0 + \beta_1 X$, where p is the probability that Y_j occurs and $\{\beta_l\}_{l=0,1}$ are the regression coefficients. These ones are estimated using the log of the maximum likelihood function such that

$$l(\beta) = \log(L(\beta)) = \sum_{i=1}^{N_1+N_2} y_i(\beta_0 + \beta_1 x_i) - \sum_{i=1}^{N_1+N_2} \ln(1 + \exp(\beta_0 + \beta_1 x_i)) \quad (1)$$

To conduct the collapsing method, two hypothesis tests are considered. The null hypothesis (H_0) states that the studied gene is not associated to the disease. In that case, β_1 equals to 0 and $\text{logit}(p) = \beta_0$. The alternative hypothesis (H_1) informs that there is an association. β_1 is not null and the logit model remains $\text{logit}(p) = \beta_0 + \beta_1 X$. Let us define a , b , c and d as the number of individuals that: have at least one variant allele on any of the k sites in controls; have at least one variant allele on any of the k sites in cases; have non variant allele on the k sites in controls and have non variant allele on the k sites in cases, respectively. In that case, (1) becomes

$$l(\beta) = d\beta_1 + b(\beta_1 + \beta_2) - [(a+b)\ln(1 + \exp(\beta_1 + \beta_2))] - [(c+d)\ln(1 + \exp(\beta_1))] \quad (2)$$

This function has a global maximum only if a , b , c and d are different from 0. The maximization of (2) under H_1 gives us $\hat{\beta}_{H_1} = (\hat{\beta}_0, \hat{\beta}_1) = (\ln(\frac{d}{c}), \ln(\frac{b*c}{a*d}))$ while under H_0 , it leads to $\hat{\beta}_{H_0} = \hat{\beta}_0 = \ln(\frac{b+d}{a+c})$. After estimating regression coefficients, the statistic test result is given by $Stat = 2(l(\hat{\beta}_{H_1}) - l(\hat{\beta}_{H_0}))$. This value being distributed according to the χ^2 distribution with 1 degree of freedom ($\chi^2(1)$), if $Stat > \chi^2(1)$, H_0 is rejected, otherwise, we can not decide whether the gene is associated to disease or not.

3. Secure collapsing method

Our framework considers three entities: a Genetic Research Unit (GRU) who owns N_1 cases; a Genomic Research Center (GRC) who has N_2 controls and a Cloud Service Provider (CSP). We assume that: *i*) all data are BGV encrypted and stored by CSP, GRU and GRC possess their own pair of keys, respectively i.e., (K_p^U, K_s^U) and (K_p^C, K_s^C) and *ii*) GRU and GRC ask CSP to perform collapsing method on their data. CSP is considered as "honest but curious". It follows the processing steps but may try to infer information about GRU and GRC data. Herein, we only focus on protecting data confidentiality and individual privacy. Other data threats are out of the scope of this paper due to space limitation. Because the collapsing method is based on some nonlinear operations that cannot be achieved with BGV (e.g., division and $\ln(\cdot)$ function), a third party entity (TPE) is introduced. It has also a pair of key (K_p^T, K_s^T) . Case data of GRU and control data of GRC correspond to VCF files. To roughly sum up, one VCF file contains a table the lines

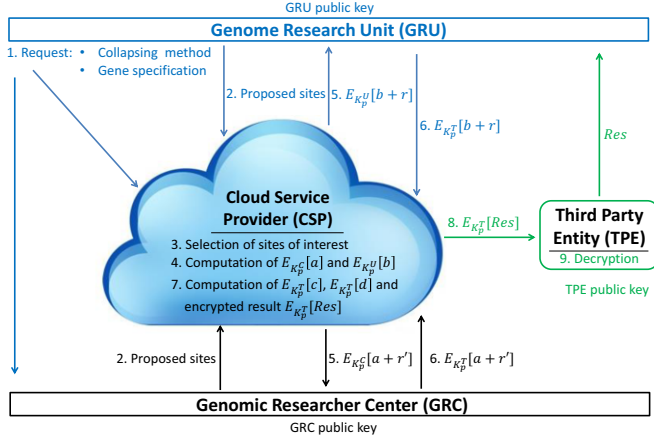

Figure 1. Different steps of our secure collapsing method

of which correspond to the variants and the columns to individuals. Each table element contains binary values. To benefit of the BGV batching property and of the fact it allows binary operations, one line is encrypted as a single message. For a test of M variants, we have two sets of encrypted vectors $\{E_{K_p^U}[v_n^{cas}]\}_{n=1\dots M}$ and $\{E_{K_p^C}[v_p^{con}]\}_{p=1\dots M}$. As shown in the Figure 1, our secure collapsing method is conducted in 9 steps as follows.

1. GRU sends a request to the CSP and GRC to initialize the test, specifying the gene he is interested in.
2. GRU and GRC choose their respective sites of interest and send them to CSP. They correspond to positions into the vectors $\{E_{K_p^U}[v_n^{cas}]\}_{n=1\dots M}$ and $\{E_{K_p^C}[v_p^{con}]\}_{p=1\dots M}$.
3. CSP selects the sites of interest in the stored samples of GRC and GRU and constructs two encrypted vectors of binary values $E_{K_p^U}[C_U]$ and $E_{K_p^C}[C_C]$ from $\{E_{K_p^U}[v_n^{cas}]\}_{n=1\dots M}$ and $\{E_{K_p^C}[v_p^{con}]\}_{p=1\dots M}$, respectively.
4. CSP computes $E_{K_p^C}[a] = E_{K_p^C}[\sum_k C_C(k)]$ and $E_{K_p^U}[b] = E_{K_p^U}[\sum_k C_U(k)]$.
5. CSP selects two random values r and r' , computes $E_{K_p^C}[r]$ and $E_{K_p^U}[r']$ and sends $E_{K_p^C}[a+r] = E_{K_p^C}[a] + E_{K_p^C}[r]$ to GRC and $E_{K_p^U}[b+r'] = E_{K_p^U}[b] + E_{K_p^U}[r']$ to GRU. This process corresponds to an additive data masking operation.
6. GRU decrypts $E_{K_p^C}[a+r]$ and GRC decrypts $E_{K_p^U}[b+r']$. Both of them re-encrypt these values using K_p^T and send the results to CSP.
7. CSP computes $E_{K_p^T}[N_1]$ and $E_{K_p^T}[N_2]$. With $E_{K_p^T}[a]$, $E_{K_p^T}[b]$, it calculates $E_{K_p^T}[c]$ and $E_{K_p^T}[d]$, and interacts with TPE to SMC computes $E_{K_p^T}[Stat]$ (see Section 2).
8. Thanks to BGV, CSP computes the encrypted sign $E_{K_p^T}[Res]$ of the encrypted difference $E_{K_p^T}[Stat - \chi^2(1)]$ and sends it to TPE.
9. TPE decrypts Res and sends the decrypted value to the GRU.

As stated in Section 2, the computation of $Stat$ requires the computation of $\ln(\cdot)$, a non-linear function. To secure it, our solution combines homomorphic encryption with an

original multiplicative data masking. It adds a noise that can be removed thanks to \ln property: $\ln(ab) = \ln(a) + \ln(b)$. Due to space limitation we cannot detail this approach.

4. Experimental results

Experiments were conducted on a genetic sample of 57 individuals (20 cases and 37 controls). These data are extracted from a real genetic database. Data are encrypted using the BGV cryptosystem implemented with HELib library. Our choice of HELib stands on the fact it optimizes the size of encrypted data to store in the cloud thanks to batching. We ran the proposed solution on a machine equipped with 4 GB RAM, Intel Core i5-5200U, 2.7GHz, running on Ubuntu 18.04 LTS. Execution time is about 15 minutes with no errors in the test results compared to the same tests conducted on clear data.

5. Conclusion

In this paper we have proposed the first privacy-preserving collapsing method using a logistic regression model. It takes advantage of fully homomorphic encryption, of SMC and multiplicative data masking in order to allow two entities to compute this test on encrypted data; data they store in the cloud without decrypting them. This solution is secure under the honest but curious adversarial model. Because our scheme makes no approximations, it achieves exactly the same results as working on clear data. Future works will focus on minimising computation complexity by exploiting parallel computing.

Semantic Querying of Hospital Data Using an Ontology-Based Model of Discharge Summaries and ICD 10

Ihssen BELHADJ^{a,1} and Thierry BOUDEMAGHE^a

^a *Department of Medical Information, Methods and Research (S.IM.M.E.R), CHU Nîmes, Univ Montpellier*

Abstract. This paper focusses on the question of knowledge-based modeling of discharge summaries for semantic requesting in the context of hospital reporting process. An ontology was designed and implemented to capture patient data and required expert knowledge. The modeling process was carried out manually using Protégé after an initial reverse engineering of the official format of discharge summaries. An OWL 2 model was built integrating discharge summaries ontology and ICD 10 hierarchy. The framework is operationalized using the OpenLink Virtuoso database system (RDF store), enabling SPARQL queries and basic reasoning features. The evaluation was performed by implementing a use case based on patient comorbidities.

Keywords. Ontologies, OWL, RDFS, RDF, ICD 10, Protégé, OpenLink Virtuoso

1. Introduction

Hospital stakeholders need business reports for medical activity analysis, decision-making and strategic planning of care. Although data analytics are valued when they are simple, concise and relevant, their production remains a complex task, requiring manipulation of referential data such as diseases and procedures that are coded using standard terminologies. ICD 10 codes [1], used in this context to express principal and secondary diagnosis, refer to detailed descriptions of disorders. These fine-grain codes are inappropriate for business reporting because they do not respond to the “summary” feature of hospital indicators. In order to overcome this issue, data scientists map ICD 10 codes to high-grain terms that are more relevant to describe care chains and in-hospital pathways. One example of such a situation is medical activity reporting according to the acuteness/chronicity of diseases or their anatomical location. Such reporting processes require concrete substantial intervention of domain experts to build code glossaries. The weaknesses of this process consist in: (1) the dependence on domain expert knowledge and points of view; (2) the deprecation of used codes that require verification over time; and (3) the lack of semantic mapping between different glossaries. This observation led us to consider that building sustainable reporting services cannot rely solely on data

¹ Corresponding Author, Ihssen BELHADJ, S.IM.M.E.R., Nîmes University Hospital, Pl Pr Robert Debré, 30000 Nîmes, France; E-mail: ihssen.belhadj@chu-nimes.fr.

management strategies. A better and simpler method should take a comprehensive approach covering the management and formalization of underlying knowledge. The objective of this work is to build and operationalize a knowledge-based model of discharge summaries that enables semantic queries regarding basic properties of disease terminology such as their hierarchical organization.

2. Material and methods

2.1. Discharge summaries data and ICD 10 hierarchy

Discharge summaries are created for each hospitalization [2]. Collected data cover administrative information such as date of entry and discharge, diagnosis information coded with ICD 10, procedures information coded using CCAM [3], and finally the *Groupe Homogène de Malade* (GHM), which is the equivalent of the diagnosis-related group. These data are uploaded monthly to a government agency named the *Agence Technique de l'Information sur l'Hospitalisation* (ATIH) to issue activity-based payments. Data are also stored in local databases for hospital reporting and evaluation studies. An official format of data is published by the ATIH providing a technical description of data to be transmitted: position, definition, type and sometimes range of possible values. Two types of data elements are distinguishable: referential data to be coded according to defined terminologies; and non-referential data that refer to elementary data type values such as integer, date or string.

This work focuses particularly on ICD 10, as it is the standard resource for disease coding. The strengths of this terminological resource are: (1) the amount of data coded with this resource; (2) its complete coverage; and (3) the hierarchical granularity of disease descriptions. The weaknesses of ICD 10 are: (1) some inconsistencies in chapters and subchapters as grouping nodes; (2) the lack of defining properties of terms; (3) insufficient semantic mapping procedures between different terms (i.e. etiology/manifestation) pertaining to its hierarchical nature; and (4) periodic updates possibly modifying the hierarchy and/or the meaning of terms [4].

2.2. Ontological modeling principles of discharge summaries using OWL 2

Ontologies provide a formalized and shared vision about domain concepts, properties and their semantic relations [1]. They provide a modeling framework to simultaneously express data and knowledge. Their usefulness consists in enabling reasoning features on complex assertions about properties and consistency checking. The ontological principles assumed in our modeling process are: (1) considering data elements in the official format as domain concepts expressed with “owl classes”, (2) discharge summaries data as instances expressed with ‘owl individual’, (3) elementary data types as ‘owl data properties’ and (4) referential data as ‘owl data object properties’. We started by reverse engineering data formats. This generated a raw OWL ontology containing the classes and object properties. This ontology was then refactored manually to add definition domains and ranges.

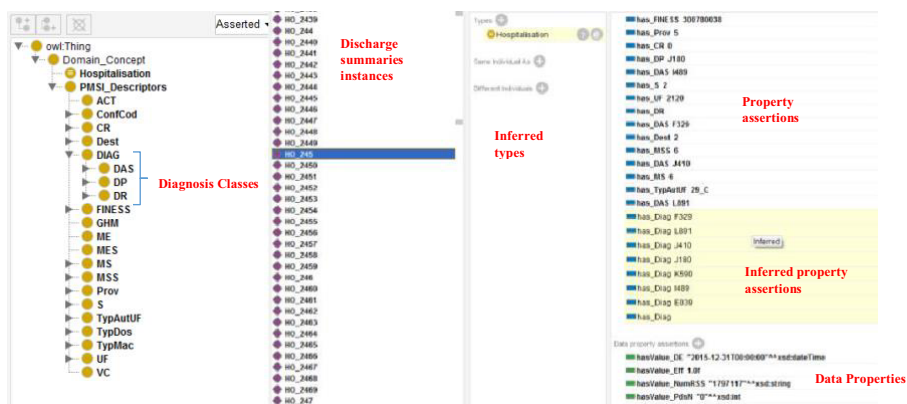

Figure 1 the OWL 2 model of discharge summaries description visualized using Protégé.

2.3. Intermediate model of the ICD 10

While terminology modeling has been addressed in detail [4,5], we focused on using the ICD 10 for its semantic information, e.g. its hierarchy, articulated with the data and allowing for semantic queries [6]. To this end, several issues had to be overcome: not only is the ICD 10 adapted for the French prospective payment system with extended codes, but this variant is also updated annually on March 1st, so an annual report should take into account two versions, not to mention multi-annual reporting.

Building on the current model of the ICD 10 released by the Organisation Mondiale de la Santé (OMS) [7] and expressed in SKOS [8], we designed an intermediate model by combining it with the French specific material:

- We retained only the hierarchical structure of the OMS (skos:broaderTransitive and skos:narrowerTransitive), stripping all other information (i.e. icd:classKind icd:CodingHint) apart from skos:preflabel, replaced by its French translation;
- Two elements were added as properties: the ICD 10 code (icdfr:code) formatted according to the French convention (code without dot); and the hierarchical level of the code (icdfr:nivH), starting from 1 for the chapter level. This information was grouped as properties of a resource <info>, <info> being itself a property of the ICD term resource;
- Starting from the 3 digit codes, we appended the French codes (e.g. including their extensions) and their hierarchical level. At this stage we had a complete French version of the ICD 10;
- Finally, we implemented a resource <version>, as a property of the <info> resource. <version> was designed with a start date, an end date and a version identifier. It was then possible to manage validity periods of the versions.

It is possible with Virtuoso to implement skos:broaderTransitive and skos:narrowerTransitive through “rule sets” associated to graphs [9]. We implemented the ICD 10 hierarchy using this functionality.

2.4. *Ontology population, data querying and reporting framework*

The reporting framework was implemented based on OpenLink Virtuoso, installed on a Windows 2012R2 Server running on an Intel Xeon E5 processor with 16 Go of RAM.

We uploaded around 340,000 triplets corresponding to the 70,000 discharge summaries of the Nîmes University Hospital for the first semester of 2019, which required querying both ICD 10 French version 2018 and 2019.

As an example, the following query retrieves in less than a second the number of discharge summaries by the ICD 10 codes of hierarchical level 2 their principal diagnosis is related to:

```
SPARQL DEFINE input:inference <http://localhost:8890/HIER>
PREFIX icdfr: <http://simmer.chu-nimes.fr/icd-fr-schema#>
PREFIX rss: <http://simmer.chu-nimes.fr/rss-schema>
SELECT DISTINCT ?ch ?lh (COUNT(DISTINCT ?NumRSS) AS ?NbRSS)
FROM <http://localhost:8890/RSS2019M06>
FROM <http://localhost:8890/REF>
WHERE
{
    ?x rss:hasValue_NumRSS ?NumRSS .
    ?x rss:has_DP ?d .
    ?d icdfr:info ?i .
    ?i icdfr:code ?c . ?i skos:prefLabel ?l .
    ?i icdfr:version ?v . ?v icdfr:ddv ?dd . ?v icdfr:dfv ?df .
    ?i skos:broaderTransitive ?ih OPTION (TRANSITIVE) .
    ?ih icdfr:code ?ch . ?ih skos:prefLabel ?lh .
    ?ih icdfr:nivH 2 .
    ?x rss:hasValue_DS ?ds
    FILTER
        (?dd <= ?ds && ?ds <= ?df)
}
GROUP BY ?ch ?lh
ORDER BY DESC(?NbRSS)
```

The combination of the `skos:broaderTransitive` property and the `icdfr:nivH` property ensures the determination of the level of aggregation. We used the R software to query the Virtuoso server and format and deliver the results.

3. Results and discussion

An ontology model of French discharge summaries was developed and expressed in OWL 2 formalism. This model is populated with large datasets available for requesting through SPARQL endpoint. SKOS model is used to implement the ICD 10 hierarchy. The whole framework supports hospital automatic reporting according to multiple criteria. Requesting data according to ICD 10 chapters or subchapters (intermediate codes that are not directly used in coding) was carried out taking advantages of reasoning features such as relation transitivity and “is-a”-property heritage.

This first step work shows the technical feasibility of the framework and lays out a path for sustainable hospital reporting services, through a sound methodology of data and knowledge management. Nevertheless, achieving such a purpose requires handling subsequent issues such as knowledge acquisition and knowledge sources consistency management.

To take into account the deeper properties of diseases will need the formalization of a knowledge-acquisition process. This raises the question of available disease knowledge sources and their evolution over time.

Protégé™ and OpenLink Virtuoso™ database systems are useful tools that help respectively to build the model and to operationalize the RDF database system. It would be useful if all Protégé reasoning features were implemented in Virtuoso™ and inversely if Virtuoso™ OWL model could be visualized via Protégé™ without ad-hoc developments.

4. Conclusion

Envisioning hospital reports through knowledge-engineering techniques has proven very fruitful, with already actionable results after this first round of exploration and development. This work enables us to identify the issues we need to explore further: enhance and refine the ontology of the discharge summaries in order to take into account not only the medical dimension but also other aspects (e.g. geographical origin of the patients and information about the hospitals); and expand the terminology modeling (e.g. procedure terminology) using the strategy we have defined to take into account the different versions.

Finally, we plan to study the national database using this approach in order to explore its capacity as an instrument for health resource usage analysis.

Supervised Bayesian Statistical Learning to Identify Prognostic Risk Factor Patterns from Population Data

Colin J. CROOKS^{a,1}

^a*University of Nottingham, UK*

Abstract. Current methods for building risk models assume averaged uniform effects across populations. They use weighted sums of individual risk factors from regression models with only a few interactions, such as age. This does not allow risk factor effects to vary in different morbidity contexts. This study modified a supervised Bayesian statistical learning method of topic modelling, allowing individual factors to have different effects depending on a patient's other comorbidity. This study used topic modelling to assess more than 71,000 unique risk factors in a population cohort of 1.4 million adults within routine data. The model learnt prognostically important risk factor patterns that predicted 5 year survival, and the resulting model achieved excellent calibration and discrimination with a C statistic of 0.9 in a held out validation cohort. The model explained 92\% of the observed variation in 5 year survival in the population. This paper validates using survival supervised Bayesian topic modelling within large routine electronic population health data to identify prognostically important risk factor patterns.

Keywords. Latent Dirichlet allocation, topic modelling, Bayesian modelling, electronic health records, co-morbidity

1. Introduction

To understand the effects of large numbers of individual factors, and how these vary in different combinations, requires a different approach from weighted linear summations of small numbers of individual factors common in current prediction models. Methods are needed in which risk factors are modelled by their observed patterns, rather than as individual factors. Bayesian statistical learning methods using topic modelling provide a more interpretable alternative to current machine learning methods for identifying unknown patterns in data[1] By using mixtures of risk factor patterns, risk factor effects can vary in different patients depending on the co-occurrence of other factors. This reflects the heterogeneity observed in the general population. Importantly, it has an advantage of transparency through the interpretable intermediate step of topics constructed from risk factor patterns. Topic modelling also has computational advantages through Bayesian learning, as it can process larger numbers of codes, whilst it incorporates priors to reduce over fitting where the data is sparse. Importantly, topic

¹ Corresponding Author: Colin J. Crooks, NIHR Nottingham Biomedical Research Centre at the Nottingham University Hospitals NHS Trust and the University of Nottingham, and Nottingham Digestive Diseases Centre, School of Medicine, University of Nottingham, NG7 2UH, UK; E-mail: colin.crooks@nottingham.ac.uk

modelling can be supervised by outcomes, including survival time [2, 3]. The aim of this study was to assess the feasibility of using survival supervised topic modelling to predict mortality from unselected population based routine health data through learning prognostically important morbidity patterns.

2. Methods

The study cohort consisted of all adults in the English population over 18 years who were alive and registered on 1st January 2010 to the Clinical Practice Research Datalink (CPRD, protocol number 16_269R was approved by the Independent Scientific Advisory Committee (ISAC)). All their routine primary care (diagnostic Read codes from the CPRD clinical file) and secondary care (ICD 10 diagnostic codes from linked Hospital Episodes Statistics (HES)) data recorded prior to 1st November 2009 were included in the study with no filtering. The two month exclusion window avoided including codes related to a final illness event. All deaths from this cohort were identified for the study outcome between 1st January 2010 and 1st January 2015. Each diagnostic code was weighted with the frequency with which it was recorded in the data for the year prior to 1st November 2010. Age was adjusted within the baseline hazard by setting age as the origin of follow up time. The cohort was divided randomly into a 50% training cohort, 25% testing cohort and 25% validation cohort using simple random sampling.

2.1. Bayesian statistical learning model - Survival Supervised Topic Modelling

Blei *et al* developed the initial Latent Dirichlet allocation method for categorising documents based on associating word frequency combinations with unobserved (or latent) topics[1], and observed topics (supervised allocation)[2]. For this study topic modelling was supervised by censored survival data, using cumulative risks predicted from survival models as previously described [3]. However, to scale this up to large but noisy and sparse electronic health record data, with tens of thousands of unique codes, this study integrated 2 further modifications into the algorithm: 1) An asymmetric Dirichlet prior that was learnt from the data, promoting uninformative but frequently occurring codes to be allocated into uninformative baseline topics, 2) A penalised Cox proportional hazards model fitted via a coordinate descent algorithm to improve stability, with automated centering of topics based on the current topic allocations.

2.2. An asymmetric Dirichlet Prior learnt from the data

High frequency but uninformative terms can, by their association with other terms, become allocated to informative topics. To reduce this an asymmetric prior for document level topic distributions was learnt from the word topic allocations [5]. This allowed some topics within the model to automatically form baseline topics with a higher prior Dirichlet probability, thus promoting patients with few or uninformative risk factors to be allocated to these baseline topics along with their uninformative risk factor combinations. This topic prior was given a Dirichlet distribution learnt using the Newton-Raphson method [5]. The baseline topic with the highest prevalence, i.e. the highest number of words assigned to it was allocated a zero coefficient in the Cox

model for each iteration. This aided the convergence of the Cox model by keeping the topic simplex centered.

2.3. A penalised proportional hazards model via a coordinate descent algorithm

To improve stability a penalty was introduced to the Cox model, shrinking coefficients towards the null, reducing instability, and preventing over-fitting where the data are sparse. Within the learning algorithm each topic is required to retain some level of probability, therefore L2 regularisation (or ridge regression) rather than L1 (Lasso) weighting was used [4]. Cyclic coordinate descent was used to fit the Cox model and the latent Dirichlet algorithm, as the large number of parameters was prohibitive for matrix inversion [4]. This also allowed coarse parallelisation of the document level updates.

3. Results

The topic model algorithm described above was applied to an unselected population cohort of training 712,868 patients derived from linked primary and secondary cared data from the English Clinical Practice Research Datalink for a range of numbers of topics from 10 to 200. The model was fitted to predict five year survival from patients alive on the 1st January 2010 using over 71,141 unique diagnostic codes available prior to 1st November 2009. The model converged on average in under 20 iterations. In addition to varying the topic number, a range of L2 penalties was assessed from 10^{-4} to 10^4 , with the best fitting selected by out of sample likelihood in cross validation during the maximisation step.

3.1. Model parameter selection

The model learnt in the training cohort was applied to the testing cohort of 356,482 patients, and the perplexity calculated as a measure of model fit perplexity is shown in figure 1. Perplexity is an average of the inverse likelihood per code, and the lower the perplexity the better the model fit. Figure 1 shows that model fit increased rapidly with an increase in topic number, but after 90 topics this plateaued. A fixed penalty of 0.01 was the minimal value that aided convergence in the test data and was selected as the L2 penalty. Fifty three of the topics were significantly associated with survival ($p < 0.05$ likelihood ratio test), and the remainder were null and uninformative.

The topics generated by the latent Dirichlet allocation demonstrated recognisable combinations of risk factors that cut across different disease categories to define clinically recognisable frailty and multi-morbidity types. Summaries of three of selected topics that were strongly associated with survival are shown in (table 1).

Figure 1. Model fit by number of topics in the testing dataset (lower is better)

Table 1. ICD and Read code descriptors with high probabilities for three example learnt topics that were strongly associated with survival

Summary	Cardiac disease, housebound, limited mobility and constipation	Cataract, falls, osteoporosis, fractures and UTI,	Chronic leg ulcers and nursing care
Read and ICD 10 code descriptors	• Congestive heart failure	• Hypertension	• Dressing of wound
	• Syncope and collapse	• Cataract	• Nursing care - dressing
	• AF & flutter	• High BMI	• Leg ulcer NOS
	• COPD	• Fall-accidental	• Cellulitis NOS
	• Senility	• Dementia	• Dressing of ulcer
	• Living alone	• UTI	• Wound healing
	• Constipation	• Osteoporosis	• Change of dressing
	• Housebound	• Fracture neck of femur	• Wound observation

3.2. Validation and calibration

The 90 risk factor topics that were learnt by the model in the training cohort were applied to the held out validation cohort (n=356,473 patients) using the inference algorithm as described by Blei *et al* [1], adjusted for age (in 10 year age bands) and gender. This model demonstrated a 1 year discrimination with a C statistic of 0.925 (95% confidence interval 0.921-0.929), which reduced to 0.908 (0.906-0.910) by 5 years. The average observed survival for each centile of the predicted topic model is plotted in figure 2. This showed excellent calibration across the range of predicted survival. 92% of the observed variation in 5 year survival was explained by the model (R^2 adjusted for censoring).

4. Conclusion

Topic modelling provides a novel Bayesian statistical learning approach to learn prognostic patterns of risk factors from routine health data, and this study demonstrates

it can be successfully adapted to censored electronic health records. This study confirmed the importance of using risk factor patterns to model risk rather than individual risk factors, and demonstrated how these different patterns of coding can be captured automatically. One limitation is the model assumed learnt patterns were independent from each other, and further work will incorporate a correlated topic model. However, the current method identified clinically recognisable risk factor patterns of multi-morbidity and frailty that would not be included in standard co-morbidity scores. This approach could be applied to identify cross cutting morbidity patterns that are necessary for prediction models with the increasing complexity of multi-morbidity in the population. The C++ code underlying this paper can be accessed at doi.org/10.5281/zenodo.1045521 or github.com/ColinCrooks/SurvivalSupervisedLDA.

Abstract. Automatic detection of ICD-10 codes in clinical documents has become a necessity. In this article, after a brief reminder of the existing work, we present a corpus of French clinical narratives annotated with the ICD-10 codes. Then, we propose automatic methods based on neural network approaches for the automatic detection of the ICD-10 codes. The results show that we need 1) more examples per class given the number of classes to assign, and 2) a better word/concept vector representation of documents in order to accurately assign codes.

Keywords. ICD-10 coding, clinical NLP, clinical narratives, French

1. Introduction

Automatic coding of clinical narratives in French with the International Classification of Diseases, 10th revision (ICD-10) has become a necessity, as ICD-10 is used for billing, epidemiology survey and many other tasks. In this work, we present 1) a corpus with French clinical documents annotated with the ICD-10 codes, and 2) methods relying on neural networks for document-level classification. Given the difficulty of this task, the aim of our work is to create a tool that suggests relevant codes to human coders.

Several shared tasks are related to the ICD coding. The first of the kind, Computational Medicine Challenge [1] in 2007, was dedicated to the assignment of the ICD-9-CM codes to clinical narratives (radiology reports). While [2] is the first work on ICD coding in French, since 2016, CLEF eHealth offers a clinical information extraction challenge which aim is to extract ICD-10 codes from health reports. Recently [3,4,5], the CépiDC task consisted in extracting ICD-10 codes from death reports in several languages (French in 2016, French and English in 2017, French, Hungarian and Italian in 2018). In 2019 [6], the task involved the automatic annotation of German non-technical summaries of animal experiments with ICD-10 codes. The 2020 task will focus on ICD-10 coding for clinical narratives in Spanish. As we are working with French clinical documents, we next describe the 2018 French data and the most efficient systems.

The French death certificates are stored in two files: one raw text file in which the physician writes the report (raw causes) and one file containing the corresponding ICD codes (computed causes). The computed causes file might contain the text supporting

line	text	normalized text	ICD codes
1	choc septique	choc septique	A41.9
2	peritonite stercorale sur perforation colique	peritonite stercorale	K65.9
2	peritonite stercorale sur perforation colique	perforation colique	K63.1
3	Syndrome de détresse respiratoire aiguë	syndrome détresse respiratoire aiguë	J80.0

Table 1. A sample document from the CépiDC French Death Certificates Corpus: aligned dataset [5]

Aligned				Raw			
Team	Precision	Recall	F-measure	Team	Precision	Recall	F-measure
IxaMed-2	.841	.835	.838	IxaMed-1	.872	.597	.709
IxaMed-1	.846	.822	.834	IxaMed-2	.877	.588	.704
IAM-2	.794	.779	.786	LSI-UNED-1	.842	.556	.670
IAM-1	.782	.772	.777	LSI-UNED-2	.879	.540	.669

Table 2. Best CLEF eHealth 2018 results on the raw and aligned French dataset [5]

the coding decisions. Two datasets were provided for this task: one raw and one aligned. The raw dataset contains the original death certificates and the corresponding computed causes. The aligned dataset contains per line: raw text, normalized text and the corresponding ICD code, as exemplified in Table 1.

The *IxaMed* team [7] used a language-independent solution in which a neural sequence-to-sequence modeling system encodes a variable-length input sequence of tokens into a sequence of vector representations, and decodes those representations into a sequence of output tokens (the ICD10 codes). As shown in Table 2, *IxaMed* got the best results on the aligned and raw datasets. The *IAM-ISPED* team [8] used a dictionary-based approach to assign ICD-10 codes to each text line, and Levenshtein distance and synonym expansion system to detect typos. *IAM-ISPED* got the second best score on the aligned dataset and third on the raw dataset. The *LSI-UNED* team [9] submitted two runs for each dataset. Their best run used a multilayer perceptron and an One-vs-Rest (OVR) strategy supplemented with IR methods. The models were trained with the training data and dictionaries of CépiDC, estimating the frequency of terms weighted with Bi-Normal Separation (BNS). *LSI-UNED* was the second best system on the French raw dataset.

The task addressed during this challenge is interesting although the death certificates cannot be considered as free-text but rather as controlled text documents. This is especially true for the aligned dataset, which makes it very convenient for the methods proposed during the challenge. In this work, we use clinical narratives containing mostly free-text, therefore, the methods used during the challenge are not appropriate.

2. Method

Dataset. Our dataset contains 28,000 clinical documents from the Rennes university hospital. Each document contains one or several notes for a single patient issued from a single stay at the hospital. Table 3 presents statistics on our corpus. As it shows, although the tokenization methods might differ, our documents are much longer than death certificates. Indeed, the latter only contain on average 3 lines, 10 tokens and 4 ICD codes per document while our clinical narratives have on average 1,345 tokens per document and twice as many codes. It also shows that a majority of ICD codes have very few examples in the corpus which will be an issue for the deep learning methods. A typical document describes the patient’s medical history, reasons for hospitalization, laboratory measurements, findings, treatment and conclusion. Our set of data also contains some noise (e.g.

	Training	Development	Test	Total
Documents	22,400	2,800	2,800	28,000
Tokens	30,307,091	3,718,715	3,654,599	37,680,405
Total ICD codes	182,112	23,010	22,561	227,683
Unique ICD codes	5,735	2,824	2,887	6,116
Unique unseen ICD codes	-	191	212	-
Codes with less than 10 examples	3,885	2,320	2391	-
Codes with 100 examples or more	382	32	31	-

Table 3. Descriptive statistics of the Rennes University Hospital dataset

phone numbers, names, email addresses, titles, etc.) which was not preprocessed. As our data contain confidential medical information, we cannot show any examples.

Tasks. The first task addressed is the multi-label classification done on a document level for all codes. As Table 3 shows, there are 6,116 different classes (ICD codes) to identify: 5,735 codes are present in the training set among which 3,885 examples have less than 10 examples. For the second task, we reduced the hierarchical level of the ICD-10 codes. All codes with 3 digits and more were reduced to 2 digits: A01.3 *Paratyphoid fever* C becomes A01 *Typhoid and paratyphoid fevers*. Therefore, only codes A00 to Z99 are exploited, which decreases the number of classes to 1,549 overall, among which 1,501 are present in the training set.

Methods. The purpose of our work is to design an approach for the automatic and efficient detection of the ICD codes. The approaches proposed and tested rely on specifically trained word embeddings and supervised learning techniques. In the existing work, various methods have been used to represent words as vectors. Recently, several machine learning-based approaches have been introduced for a better representation of semantic relations between words. We experiment with fastText vectors [10], which use subword information to represent words missing in the training vocabulary. Each word is represented as a bag of all possible n-grams of characters it contains. Our model is trained on our dataset with the *Skip-Gram* algorithm, 300 dimensions, a window of 5 words before and after each word, a minimum count of five occurrences for each word and negative sampling. Besides, we experiment with two neural network architectures: recurrent and convolutional. A recurrent neural network is a class of network which is capable of adapting its decision by taking into account the previously seen data, in addition to the currently seen data. This operation is implemented thanks to the loops in the architecture of the network, which allows the information previously seen (previous words) to persist in memory. In our experiments, we used a bidirectional recurrent neural network with long short-term memory cells (BiLSTM). Convolutional neural networks (CNN) are widely used in Computer Vision and Natural Language Processing. The convolution layer consists of a set of filters, where each filter is convolved with the input forming feature maps. These filters are randomly initialized and become parameters that will be learned by the network.

Experiments. We trained several CNN models based on the architecture proposed in [11] for 30 epochs. We used four filter windows (2, 3, 4 or 5 width) with either 100, 500, 1,000 or 2,000 feature maps each (ReLU activation), 0.5 dropout, global max pooling and a fully connected layer with ReLU activation of either 100, 1,000 or 2,000 dimensions for a more compact representation. Regarding our BiLSTM, the dimensionality of the

output space was set to 600 units per layer (backward/forward) with 0.5 dropout. Both architectures use our pre-trained fastText vectors with 0.5 dropout and a fully connected sigmoid layer for prediction. Performance was measured with the standard metrics: precision, recall and F-measure.

3. Results

As Table 4 shows, on both tasks, our CNN, even at the lowest settings, performs better than our BiLSTM. Our experiments also show that increasing the number of feature maps per convolution filter and hidden units in the fully connected layer both improves the results. Indeed, we get an 8.21 point increase at the most expensive settings when compared to the lowest settings. We might be able to slightly improve the results if we raise parameters further. However, it would be a low increase with a great computing cost. Indeed, the results on Task 2 show a very low improvement (0.28 point) when doubling the value of the parameters.

	System	Feature maps	Hidden units	Precision	Recall	F-measure
Task 1	BiLSTM	-	600	0.6513	0.1387	0.2287
	CNN	100	100	0.6510	0.2091	0.3165
	CNN	100	1,000	0.4916	0.2491	0.3306
	CNN	500	100	0.5624	0.2652	0.3605
	CNN	500	1,000	0.4935	0.3042	0.3763
	CNN	1,000	100	0.5353	0.2597	0.3498
	CNN	1,000	1,000	0.5052	0.3200	0.3918
	CNN	2,000	2,000	0.5029	0.3301	0.3986
Task 2	BiLSTM	-	600	0.6309	0.2837	0.3914
	CNN	1,000	1,000	0.6306	0.4427	0.5202
	CNN	2,000	2,000	0.6018	0.4625	0.5230

Table 4. Results for the ICD coding tasks. The results are given in terms of Precision, Recall and F-measure. The best scores are in bold.

4. Discussion

As expected, we get better results on our second task which shows that the reduction of the number of classes is efficient. However, as we can only assign each class once to a document, we might lose some information as a document can have multiple codes belonging to the same hierarchically higher class. Besides, we get much lower results than the systems presented at CLEF eHealth 2018. This can be explained by the nature of the documents: short, structured death certificates cannot be compared to clinical narratives with free text. The tasks are therefore different. Another explanation is that some codes might not be explained by the textual data but rather by the structured data in the hospital database.

5. Conclusion

The interest for the automatic detection of ICD-10 codes has increased in recent years. Yet, the data used in previous shared tasks do not seem representative of real clinical

narratives. In our work, after a brief reminder of the existing work, we presented a new body of French clinical narratives annotated with the ICD-10 codes. Another contribution of our work is the exploitation of fastText vectors and neural networks for the automatic ICD-10 coding. The experiments are conducted and evaluated on French clinical narratives (free-text), which have not been experienced much in the previous work of this type. From a more technical point of view, our work also indicates that the convolutional neural architectures are more efficient than the recurrent neural architectures for the multi-label classification. We plan to improve our neural network performance by providing a richer feature set. Indeed, adding available structured data and using recent embedding techniques, such as BERT [12], may provide more accurate representation of the documents.

Acknowledgments. This work was partly funded by the French government support granted to the CominLabs LabEx managed by the ANR in Investing for the Future pro-gram under reference ANR-10-LABX-07-01.

Abstract. Recent studies in the biomedical domain suggest that learning statistical word representations (static or contextualized word embeddings) on large corpora of specialized data improve the results on downstream natural language processing (NLP) tasks. In this paper, we explore the impact of the data source of word representations on a natural language understanding task. We compared embeddings learned with Fasttext (static embedding) and ELMo (contextualized embedding) representations, learned either on the general domain (Wikipedia) or on specialized data (electronic health records, EHR). The best results were obtained with ELMo representations learned on EHR data for the two sub-tasks (+7% and +4% of gain in F1-score). Moreover, ELMo representations were trained with only a fraction of the data used for Fasttext.

Keywords. Natural Language processing, Contextual word embeddings, Natural language understanding

1. Introduction

The recent advances in language representation such as static word embeddings [1,2], and contextual word embeddings (e.g. ELMo[3]) led to a significant performances improvement in natural language understanding (NLU). These methods can take advantage of large text corpora to learn a representation of the vocabulary in the vector space according to words semantics and syntactic use[1]. These approaches are unsupervised: they do not require learning datasets with manual annotations. However, the training corpus must be large enough to learn a correct representation. For example, it is customary to use a full dump of Wikipedia® to learn the models[1–3]. In the biomedical domain, the vocabulary is very specific. Moreover, when looking at clinical reports in electronic health records (EHRs), the syntax is also different from articles from sources similar to Wikipedia. A recent study from Wang *et al.*[4] evaluated the performances of embeddings learned on Wikipedia, biomedical publications and clinical notes in English : learning embeddings using clinical notes from EHRs increased the performances. Would this improvement also be true for contextual word embeddings? Nonetheless, it may be challenging to have access to the large number of documents requested (*e.g.* more than 100k patients in the study of Wang *et al.*) or even have access to embedding matrices learned on such corpus, due to privacy issues. It is possible that using more advanced methods to learn the word representations such as

ELMo compared to static embeddings would allow researchers to use embeddings learned on general domain corpora and still obtain good performances.

The aim of this work is to explore the impact of the method and data source of embeddings in the context of a weakly supervised NLU task in French. For this task in a restricted domain (biomedicine), we focused on the two NLU tasks: slot-filling and intent classification.

More specifically, this task aims at providing NLU in a virtual assistant in French for clinicians to explore biological tests results information in the patient's record in natural language (e.g. *Donne moi le dernier résultat de créatinine* 'Give me the last result of creatinin'). The set of queries that a physician may have about characteristics and results of a patient is broad and diverse. Therefore, enabling queries in natural language may help accessing information more efficiently. Given that no public dataset is available for this task in French, we used a weakly supervised approach by generating training data from question templates, terminologies and paraphrases as described in a previous work [5].

We compared the performances of two types of word representations: static word embeddings (Fasttext) and contextualized word embeddings (ELMo). For each method, we also compared two different learning sets in French: #1 Wikipedia or #2 a set of 1M clinical notes from our local EHR.

2. Methods

2.1. Embeddings

We compared two types of embeddings: #1 continuous skip-gram model with sub-word information as implemented in fastText[2], #2 embeddings from language models (ELMo) where the vectors are learned from the internal states of a deep bidirectional language model[3]. As a baseline, we use a continuous skip-gram model learned only on the training set (no external dataset).

We also compared the performances of these methods when learned on either a general domain dataset or a specialized dataset. The general domain dataset (hereafter, Wiki) is made of a dump of the French version of Wikipedia plus the French dataset of CommonCrawl. For this dataset, we used pre-learned models for French downloaded from fasttext website¹ for Fasttext and from github² for ELMo.

The specialized dataset (hereafter, EHR) is constituted of a random set of 1M clinical notes from the clinical data warehouse of Necker – Enfants malades hospital, a French AP-HP childrens hospital in Paris[6]. This dataset contains 162M tokens and a vocabulary of size 92k. For Fasttext, we used vectors of 300 dimensions and a window-size of 5. For ELMo, we kept only a subset of the EHR data (24M tokens) due to the high training time of ELMo. To compare embeddings from different sources, we kept the hyper-parameters as described in [3].

¹ <https://fasttext.cc>

² <https://github.com/HIT-SCIR/ELMoForManyLangs>

2.2. Task

We evaluated the impact of the different embeddings approaches on the task of NLU in a virtual assistant (VA task). Given that no public dataset is available for this task in French, we used the dataset generated from templates, terminologies and paraphrases as described in a previous work [5]. The training dataset contains 16,000 questions, 144k words (mean length of a question is 9), the development set of 4,000 questions for the tuning of the models. For the evaluation, we collected from physicians in our hospital, a set of 178 questions that they would like to ask in such a system. This set of questions has been manually annotated.

The slot filling task (VA-sequence) consists of a sequence labeling task aiming at identifying, in the question, the labtest mention (e.g. *créatinine* ‘creatinin’) and the date- related information (e.g. *22/04/2012*, *depuis 4 semaines* ‘for 4 weeks’). In the training set, the number of distinct lab mentions was 336 with a length ranging from 1 to 11 tokens and a median length of 2. In terms of vocabulary, there is only an overlap of 28% between the training set and the test set for labtest mentions. The date labels include exact dates, relative dates and time ranges.[5]

The intent classification task (VA-classification) is divided into 4 sub-tasks corresponding to 4 axes of classification. For each utterance, we assign one label per axis. Two axes concern the results of the lab exams (*i.e.* the type of result (5 categories) and interpretation of the result (5 categories)). The two latter concern temporal aspects (*i.e.* the time of result (3 categories) and constraints on time (4 categories)).[5]

2.3. Models

We evaluated 5 different configurations of embeddings: continuous skip-gram model of 300 dimensions (D) learned on the training set; fasttext of 300D learned on Wiki; fasttext of 300D learned on EHR; ELMo of 1024D learned on Wiki; ELMo of 1024D learned on EHR.

For the sequence labeling task (VA-sequence), we used a recurrent neural network (RNN) based on bidirectional long short term memory units (biLSTM)[7]. We used two layers of biLSTM of size 256.

For the classification tasks we used a convolutional neural network (CNN)[8]. The model contains a 1D convolutional layer of 250 units, kernel size of 3, ReLU activation, followed by a max pooling layer and a dense fully connected layer.

All the models were implemented using Keras, with a Tensorflow backend, and the optimizer was Adam. We used dropouts after the embedding layer and before the final dense layer as well as L2-regularization on the convolutional layers to limit overfitting. We used a weighted F1-score (harmonic mean of the precision and the recall) to evaluate the results of the different models. To estimate the variability of the performances, we used 10 repetitions of 5 fold cross-validation on the test set.

3. Results

All the results are presented in Table 1. For the sequence labeling task (VA-sequence), the best results are obtained with ELMo learned on EHR with a F1-score of 0.76 (95%CI [0.74-77]) compared to Fasttext on EHR (0.67, 95%CI [0.61-0.73]). Interestingly, we

show similar results between ELMo on Wiki (0.69, 95%CI [0.67-0.70]) and Fasttext on EHR (0.67, 95%CI [0.61-0.73]). To note, the distance between the training set and the test set, estimated using the perplexity of the n-gram model, is 194.

Table 1. Results for the NLU task for the virtual assistant: sequence labeling (Bi-LSTM) and intent classification (CNN)

Method	Sequence labeling	Intent classification
	F1-score [95%CI]	Mean F1-score [95%CI]
Baseline (only training set)	0.62 [0.61-0.64]	0.62 [0.58-0.65]
Fasttext on Wiki	0.69 [0.67-0.70]	0.52 [0.49-0.55]
Fasttext on EHR	0.67 [0.61-0.73]	0.66 [0.63-0.69]
ELMo on Wiki	0.69 [0.67-0.70]	0.49 [0.46-0.52]
ELMo on EHR	0.76 [0.74-0.77]	0.70 [0.67-0.73]

For the intent classification task (VA-classification), again, the best results come from the ELMo model learned on EHR (F1-score 0.70, 95%CI [0.67-0.73]) compared to the second-best Fasttext on EHR (F1-score 0.66, 95%CI [0.63-0.69]). In this task, the models learned on Wiki performed poorly: Fasttext on Wiki with a F1-score of 0.52 (95%CI [0.49-0.55]) and ELMo on Wiki 0.49 (95%CI [0.46-0.52]) with a baseline at 0.62 (95%CI [0.58-0.65]).

4. Discussion

The use of pre-learned embeddings may improve substantially the results on certain downstream tasks. As shown by Wang *et al.* [4] on various tasks in English, we show increased performances on two of three tasks in French when using pre-learned embeddings on a large corpus of clinical notes. The higher improvement was obtained on the VA-sequence task suggesting that tasks requiring extended lexicons may benefit the most of the pre-embeddings. Indeed, the identification of labtest mentions highly depends on the vocabulary available during training and we show that 72% of the mentions in the test set are absent from the training set. In this scenario, the representations learned on a large specialized dataset helped the model to obtain a better generalization when dealing with previously unseen mentions.

The test set shows 29% of out of vocabulary words overall. It may also partly explain the improvements observed on the classification task also (VA-classification). Interestingly, in the VA-classification task, both embeddings (Fasttext and ELMo) learned on Wiki did worsen the results compared to the baseline. This noise might come from the lack of specialized vocabulary in the Wiki corpus and a different usage of specialized words that may vary depending on the biomedical context and that are not taken into account in the general domain.

Sheikhshab *et al.* [9] evaluated ELMo embeddings on named entity recognition tasks in the biomedical domain. They also showed improved results when using an in-domain corpus to train ELMo (*i.e.* articles from Pubmed). It would be interesting to evaluate ELMo embeddings learned on a corpus of biomedical article in French but collecting such a corpus may be challenging.

This study has some limits. First, the embeddings learned on EHR came from a single hospital. This may cause some bias in the results given that the semantic particularities of the different practices may have an impact on the suitability of the embeddings for the different tasks. One possible solution to tackle this issue would be to

learn embeddings from multiple sites. However, due to privacy issues, it is not possible to transfer massive amount of hospital data. Two other approaches might be used to workaround this issue and should be explored for the biomedical domain: #1 the use of federated learning to train the models without moving the data[10]; #2 learning one embedding per site and aligning the different embeddings using unsupervised techniques. Finally, it is not obvious to determine the size of the training corpus for an embedding. It is a common practice to use all the articles from Wikipedia for example. But do we need that amount of data in a specialized domain? Comparing the impact of the size of the embedding corpus on downstream task will be of great interest.

5. Conclusions

Depending on the task, embeddings learned on large corpora can have a significant impact on NLP tasks in the biomedical domain in French. Moreover, learning these embeddings on clinical notes will increase the performances compared to general domain. As it may not be feasible to access a large corpus of clinical notes, it is still profitable to use advanced methods such as ELMo learned on general domain and obtain reasonable results. When the task does not rely on a large specialized vocabulary, the impact of external embeddings might be reduced.

The LOINC Content Model and Its Limitations of Usage in the Laboratory Domain

Cora DRENKHAHN^{a,1} and Josef INGENERF^{a,b}

^a *Institute of Medical Informatics (IMI), University of Lübeck, Germany,*

^b *IT Center for Clinical Research, Lübeck (ITCR-L), University of Lübeck, Germany*

Abstract. To unambiguously encode the semantic meaning of laboratory tests, the LOINC terminology is widely used. With regard to the constantly changing and diverse requirements of the laboratory domain, LOINC's long-established content model and related publications are reviewed conjointly, revealing some obstacles for flexible adaptation in terms of new or varying application needs as well as issues regarding the comprehensive reusability of lab data. In a concise overview, four specific limitations are identified that require adaptation or the usage of other terminologies.

Keywords. Terminologies, Semantic Interoperability, Clinical Laboratory

1. Introduction

Logical Observation Identifiers Names and Codes (LOINC) is one of the most notable and well-known terminologies in medicine and widely used for standardized coding of laboratory data in electronic health records [1]. LOINC's content model has remained unchanged since its beginnings [2] but is confronted with varying needs and requirements in modern healthcare. Here, the significance of laboratory diagnostics entails a great diversity of tasks in digitalized lab environments including order/entry of tests and reporting of their results. Distributed laboratory data often needs to be integrated as well, for example to compare a patient's test results for clinical monitoring or to aggregate and analyze data on a larger scale in a data warehouse. In all of these aspects, economic considerations are highly relevant as well, with the billing of lab procedures being part of everyday clinical practice [3]. Like all subdomains of medicine, the laboratory field is subject to constant change, but here the rapid emergence of new diagnostic tests and methods, for example in molecular genetic analysis, speeds up this process in particular [4].

In this paper, LOINC's properties are analyzed regarding the current challenges in the laboratory domain to identify present limitations of its appliance. Related recent research is incorporated to bring together individual insights for a thorough and accurate overview. This evaluation shall not be misunderstood as criticism of LOINC – its usefulness in coding lab tests is undeniable; instead we identify potential for

¹ Cora Drenkhahn, Institute of Medical Informatics, University of Lübeck, Ratzeburger Allee 160, 23538 Lübeck, Germany; E-mail: c.drenkhahn@uni-luebeck.de.

improvement and cases in which another coding system such as the comprehensive ontology SNOMED CT is needed to fully cover the complex demands of laboratory medicine.

2. Material and Methods

Based on the authors’ extensive knowledge gained in previous projects, the LOINC content model and the features of its current version 2.66, as well as related literature, are critically reviewed in the context of requirements in modern laboratory diagnostics.

2.1. LOINC content model

Since its inception, LOINC is published biannually by the Regenstrief Institute as a database of unique codes associated with human-readable terms. Each code corresponds to a distinct lab test (currently 55,844 out of 91,388 codes) or another clinical observation explicitly defined by five mandatory main dimensions plus an optional method part. Therein, LOINC’s referenced properties are restricted to those required for a correct test result interpretation so that each combination represents the minimal set of values needed to distinguish this test from all others. For most axes, some further information can be included in specific subcomponents if needed for a full definition.

Component describes the kind of substance or analyte measured stating the test’s most basic information with an immense variety of possible values (currently 24,707 part codes) and complexity of contents (up to three subcomponents).

Property denotes in which characteristic or type of property the component was measured, e.g. as number, as substance concentration or the qualitative presence. Obviously, this value is highly correlated with the test result’s unit which is *not specified* in the LOINC term [5]. With 135 different options, the property axis is known to cause misunderstandings and therefore issues while mapping to LOINC [6].

Time is used to differentiate measurements at a single point of time from those over a (specified) interval of time with an optional subcomponent.

System defines the specimen or material sample used for testing as the second most distinct characteristic. Further refinement is typically needed by other properties (e.g. 32 LOINC codes for “creatinine” in “urine”) or a subcomponent.

Scale broadly differentiates between quantitative, ordinal and nominal measurements, forming an interrelation to the *Property* part. Answer options for qualitative tests shall be coded with SNOMED CT; for quantitative results exemplary value ranges and units are partially mentioned but not explicitly defined.

Method information is only included if the measurement technique is clinically significant by affecting the test’s result or reference range. So, most terms (63.32%) lack this dimension.

Table 1. Some exemplary LOINC codes with their defining characteristics of six dimensions. Subcomponents are divided by the ^ sign.

LOINC code	Component	Property	Time	System	Scale	Method
14682-9	Creatinine	SCnc	Pt	Ser/Plas	Qn	
14684-5	Creatinine	SRat	24H	Urine	Qn	
5802-1	Nitrite	PrThr	Pt	Urine	Ord	Test strip

14754-6	Glucose^1H post 50 g glucose PO	SCnc	Pt	Ser/Plas	Qn
14578-9	AB0 group	Type	Pt	Bld^BPU	Nom

Structure and content of terms and subcomponents as shown in Table 1 reveal LOINC's origin to work conjunctively with the syntactic interoperability standard HL7 v2. Omitted information like result value, unit, reference range or context are meant to be communicated in other fields of the HL7 v2 message or the (newer) HL7 FHIR Observation resource. Another design principle states to only add sensible combinations required in practice [2,7], limiting availability to existing pre-coordinated terms.

2.2. Related research

In a previous project, we investigated the mapping of laboratory services contained in an internal catalog of a German hospital to a standardized terminology. Internal catalogs capture the local range of services and are thus used for billing purposes. This leads to a primary focus on methods and environmental information, whereas measurement parameters like specimen or property are seldom mentioned. Because of this, we found it impossible to map the heterogenous contents to LOINC due to the small overlap of included information and the prerequisite to use complete pre-coordinated terms. As a solution, SNOMED CT could be utilized based on its concepts of diverse granularity and ability for post-coordination [8].

In a literature review, we found 929 publications since 2017 mentioning the terms 'LOINC', 'laboratory' plus 'limitations' or 'challenges' and further investigated 25 of these classified as most relevant by Google Scholar. Two articles covered the most relevant aspects for our review. Bietenbeck et al. assessed three terminologies including LOINC and SNOMED CT for their ability to encode laboratory results of different complexity and correlated evaluation parameters. Whereas LOINC was found to be easily usable, interpretive comments like measurement uncertainty or reference intervals could not be expressed adequately. With SNOMED CT more content could be encoded although full coverage remained elusive. Another issue concerning LOINC was detected in the non-existent formal definitions – and explicit hierarchies in particular – resulting in unclear (subclass) relations between terms and limited possibilities of computational analysis [9]. Stram et al. conducted a comprehensive evaluation of current challenges in LOINC usage in pathology laboratories. Among other results, an increased risk for mismatches between laboratories due to inconsistent mapping, especially of method properties, was revealed. Additionally, molecular genetic diagnostics were identified to pose serious problems on the current content model regarding the vast quantities of singular tests with heterogeneous features involved, e.g. for 22,000 genes. Rapidly evolving subdomains like this were also mentioned to be challenging for keeping LOINC up to date [10].

3. Results

Putting LOINC content model characteristics into the context of current challenges in lab diagnostics reveals four types of limitations and their underlying causes:

3.1. *Billing*

Although the billing of laboratory procedures is highly correlated with the creation of test results and thus combined evaluations may be of interest, both applications require different sets of attributes and can not easily be integrated with the same terminology as shown in [8]. These results can be transferred to the general scope because LOINC's usage-specific content model offers no means to reasonably represent billing data, primarily because of its limitation to precoordinated combinations. The enforced usage of five axes that are partially irrelevant for economic purposes whereas intentionally omitting billing-relevant methods lead to an unsuitable data model.

3.2. *Context and interpretive comments*

By examining the historic origin as an addition to HL7 standards and the coverage of its accordingly developed content model, LOINC turns out to be not intended as a standalone format to fully describe laboratory test results. Additional information referring to test environment, device characteristics or result specific comments are meant to be communicated with relation to but outside of the term. So, the attempt to interpret laboratory data exclusively based on LOINC code and result value is inherently futile.

3.3. *Aggregation of test results*

Test results sharing the same LOINC code cannot ensure a simple and correct integration for combined analysis due to some distorting factors. As explained in section 3.2, LOINC terms are lacking some crucial information for complete result interpretation, e.g. different devices and reference ranges leading to incomparable results. Furthermore, seemingly identical tests specified by the same LOINC code may actually refer to different observations caused by an inaccurate mapping of idiosyncratic terms in the first place. Here, the (necessary) complexity of the content model with subcomponents and obscure *Property* values can be identified as a source of error. During mapping, another issue arises from non-existent formal definitions and explicit hierarchies so that easily locating related terms of different granularity (e.g. with a specified method) is prevented. The missing formal conceptualization further restricts advanced aggregation as well. Otherwise, LOINC terms differing only in the *Property* axis may be principally evaluated together when their units of measurement are convertible into one another but both unit defining relations and conversion support are currently missing.

3.4. *Molecular genetics and other rapidly changing domains*

Because of the limitation to reviewed pre-coordinated terms, LOINC can hardly keep up with newly developing tests and methods. Restricting contents to sensible combinations has obvious advantages in terms of data quality and error prevention but sacrifices any flexibility on the other hand. This rigid content model does not scale well for the numerous and diverse tests required for genetic diagnostics.

4. Discussion

In a complex field of application like the laboratory domain, the presented list of limitations is obviously non-exhaustive, instead we focused on the apparently most urgent issues. An application of LOINC for billing purposes is clearly out of its predefined scope but has previously been discussed and is not far-fetched. For most of the above-mentioned challenges (billing, context, and aggregation), SNOMED CT provides an approach for improvement based on its larger coverage and ontological features, but no complete solution either [8,9]. A combined usage of both terminologies is explicitly favorable. Of course, improvements to LOINC are continually proposed and implemented as well, e.g. we recently developed an ontological representation including LOINC's implicit hierarchies [11], Hauser et al. introduced an automated process for unit conversion of compatible codes [12], and the HL7 Clinical Genomics Work Group published an implementation guide for genetic test reporting with LOINC [13].

5. Conclusion

The long-established content model of LOINC partially restricts the coding system's usefulness for derived, originally not-intended applications needs, for changing demands as well as for test result interpretation and aggregation. This is due to its inflexibility, lacking formalization and incomplete information. LOINC is no all-purpose, standalone format but can benefit largely from further specification, extension and combined usage with other terminologies, primarily SNOMED CT.

Abstract. Current high-throughput sequencing technologies allow us to acquire entire genomes in a very short time and at a relatively sustainable cost, thus resulting in an increasing diffusion of genetic test capabilities, in specialized clinical laboratories and research centers. In contrast, it is still limited the impact of genomic information on clinical decisions, as an effective interpretation is a challenging task. From the technological point of view, genomic data are big in size, have a complex granular nature and strongly depend on the computational steps of the generation and processing workflows. This article introduces our work to create the openEHR Genomic Project and the set of genomic information models we developed to catch such complex structure and to preserve data provenance efficiently in a machine-readable format. The models support clinical actionability of data, by improving their quality, fostering interoperability and laying the basis for re-usability.

Keywords. genomic models, openEHR, mutations, variations, structured data

1. Introduction

Within the healthcare domain, Next Generation Sequencing (NGS) data sets are a potential asset of clinically valuable information that, if properly read and deciphered, can pave the way for life-enhancing applications such as personalised therapeutic treatments or early detection of certain hereditary diseases, just to name a few. However, handling genomic data is a very complex task from both clinical and technological perspectives. Several initiatives are addressing the technological challenges [1,2], but they are mainly focused on the exchange aspects, while many facets of the subject still remain unaddressed. In the first place, genomic information is composed of many levels, derived from each calculation step, but usually the intermediate results are expressed in a wide variety of text file formats (e.g., SAM/BAM, VCF, etc.), thus hindering the efficient re-use, sharing and possible inclusion of data in an electronic health record (EHR). In addi-

¹Corresponding Author: Cecilia Mascia, C/O CRS4, Loc. Piscina Manna - Edificio 1, 09050 Pula (CA), Italia; E-mail: cecilia.mascia@crs4.it.

tion, bioinformatic workflows typically rely on many external resources (e.g., reference genome sequences, biological annotation databases, analysis tools) that evolve rapidly and have a significant impact on the final results. Hence, it is essential to capture the details of each workflow execution to ensure, for instance, accurate data auditability and reproducibility or to make results comparable when a different pipeline is used.

The availability of NGS data in a structured and machine-readable format would therefore facilitate their integration into effective clinical actions, thanks to the possibility of capturing granularity and provenance. This need has motivated the creation of genomic models in the form of openEHR archetypes [3,4], fostering the foundation of the Genomics openEHR modelling group – consisting of members from the CRS4 (Italy), the HiGHmed Consortium (Germany), the EUCANCan project (EU, Canada), the CINTESIS group (Portugal), the BigMed project (Norway) and the international openEHR Clinical Modelling Program [5]. This article describes how our collaborative work led to the launch of the openEHR Genomics Project, the results obtained so far and the future directions.

2. Method

2.1. The OpenEHR Approach and the OpenEHR Clinical Modelling Program

OpenEHR is set of open specifications for structured data, designed to represent medical knowledge separating domain semantics from any specific technology [6]. OpenEHR archetypes are the maximum set of attributes describing a clinical concept in a machine-readable format. They enable to represent concepts of different scale of granularity, to add specific constraints on elements and to embed their semantics. Conceptual models are formalised in computable entities through the Archetype Definition Language (ADL), which can be easily converted to a number of other popular formats like XML. The OpenEHR framework also includes a mechanism to aggregate archetypes in use case-oriented structures (i.e., templates), a query language optimised for archetypes (i.e., AQL-Archetype Query Language), a set of open APIs and a conformance test approach to validate real implementations.

The openEHR Clinical Modelling Program gathers clinicians, researchers and implementers in an international collaborative action for the development of multilingual archetypes and templates. The direct involvement of domain experts in the design process is one of the key strategies adopted to obtain high quality models, whose re-use is encouraged. Archetypes are collaboratively reviewed and made available to the community through the international Clinical Knowledge Manager (CKM) [7] – the openEHR artefacts repository – which has also some national instances developed to meet specific demands.

2.2. The Initial Genomic OpenEHR Archetypes Collection

The starting point was the set of 11 archetypes proposed in [3] that should be used within the *Laboratory test result* archetype to represent genetic test results, developed on the basis of the Variant Calling Format (VCF) file specification [8]. VCF files consist of a set of rows each describing a variation that occurred in a sample sequence together with

customisable functional annotations like, for instance, '*transcript features*' and the '*predicted impact*'. Within the archetypes, mutations are described according to the Sequence Variant Nomenclature² of the Human Genome Variation Society (HGVS) [9]. Further, the models included elements like the '*conservation score*' and the '*allele frequency*' that are usually not included in the medical report itself, but are potentially relevant on the bioinformatics research side. Finally, each tool or external database used in the analysis can be tracked by explicitly recording their name, version and, where appropriate, URL, thus integrating provenance within the data.

The Design Process

Two use cases drove the creation of a common semantic data model for the representation of variant information derived from whole genome and exome sequencing (WGS, WES) data:

- Rare Diseases: to identify pathogenic variants responsible for rare diseases through WES tests of patients and their parents.
- Oncology: to enable an evidence-based and better informed diagnostic and treatment design, based on molecular stratification.

The whole design process has been guided by the co-chairs of the openEHR Clinical Modelling Editorial Group (CMEG), responsible for the modeling governance within the community.

The first step was the rethinking of content and structure, when the whole set of nodes constituting the archetypes have been assessed from two opposing perspectives. Starting from the overall picture, we prepared a mind map (using the collaborative tool XMind³) to depict all the necessary pieces of information describing the use cases, to detect possible repetitions or overlapping with existent archetypes and to simplify the structure. Starting from the single nodes, we checked the adequacy of the concept name, its adherence with standard nomenclatures and the consistence with the element's description, adding examples to clarify the intended usage.

After reaching a good level of agreement, working with the Archetype Designer⁴, we converted the mind maps into archetypes, taking further decisions on data types, node occurrences and constraints and adding, when possible, bounds to external standard ontologies.

3. Results

On April 2019, the Genomics Project⁵ was officially created in the openEHR CKM. The project collects and makes publicly accessible the 13 archetypes developed in this work.

The *Genetic variant* is the core archetype designed to be nested within the *Laboratory test result* to report observations and annotations related to mutations found in the genome as the result of a sequencing test. The morphological description of the muta-

⁵CKM Genomic project: <https://ckm.openehr.org/ckm/#showProject=1013.30.50>

tions – i.e., nucleotide changes and genomic coordinates – is given at the DNA level with reference to a genomic reference sequence. The model supports all the simple change types identified in the HGVS guidelines [9] plus translocations and copy number variations – two structural variations that are often relevant in cancer studies. In addition, further descriptions of the mutations are possible at the transcript level in terms of changes in the coding sequence ('DNA changes') and in the protein ('amino acid changes'). The reference sequence used to annotate the variations is explicitly recorded too, through a dedicated archetype (*Reference sequence*). The archetype design allows the recording of annotations for each transcript affected by that specific mutation, pointing out the one with the highest predicted impact, considered relevant for the clinical evaluation. In this regards, the functional interpretation of the variants can be specified following the ACMG classification [10] or by citing relevant scientific literature. All the external resources used by the data analysis pipeline, including biological databases and software, can be explicitly recorded by giving their IDs, version and, possibly, a unique resource locator (URL); an archetype is dedicated to capturing this information in a structured manner (*Knowledge base*). In order to clearly state the concepts' semantic and improve data quality and interoperability, most of the model's nodes are codified using LOINC⁶, an international standard ontology for identifying health measurements, observations, and documents.

OpenEHR's flexibility allows to project the archetype data onto a variety of different use cases, enabling to archive all the elements automatically captured during pipeline execution, but presenting to the final user only those relevant to the task at hand. To demonstrate how the archetypes can be combined and integrated, an example template for a generic sequencing test report has been included in the Project.

The initial review round of the *Genetic variant* archetype started on April 26 2019, and, afterwards, we commenced in staggered steps the review process of each archetype, inviting all the interested domain experts in the project to give their opinions and comments. The process is managed by the project editors and performed completely via the CKM, which also allows the tracking of archetypes changes. At the moment of writing, one archetype has been published after one review round while the others are still in the consolidation phase. In the meantime, the Norwegian translations of the archetypes are currently being refined.

4. Discussion

The focus of our work was the creation of information models to capture genomic data for clinical and research applications. The openEHR community has overall expressed a good consensus on the structure of the models, together with a series of useful feedbacks. For instance, a series of suggestions has been provided to improve the coverage of the genomic domain, particularly with respect to the representation of complex mutations, such as splicing variants affecting RNA sequences, which are not yet supported by model. The review process has also provided important hints on how to improve and extend the usability of the models in real contexts, as a set of suggestions emerged to refine the requirements and to generalise the models towards different use cases than those

⁶Logical Observation Identifiers Names and Codes (LOINC): <https://loinc.org/>

initially considered. The feedback will be integrated in the next versions of the models while trying to balance the different perspectives.

More generally, the number of reviewers involved in this specific CKM domain tend to be fewer than those involved in more long-standing ones. We believe this is mainly due to the novelty and the specialised nature of the project, and that the situation can be improved with targeted actions to disseminate the potential of the obtained results.

5. Conclusion and Future Work

In this work we presented the openEHR Genomics Project and its first results: the models to represent clinical genomic data and its provenance with a set of openEHR archetypes. These results have been developed through a collaborative process supported by the openEHR Clinical Modelling Program. Capturing the complexity of genetic information remains a challenging task, but the results presented in this work are the promising starting point for an ongoing development and improvement process. Our next steps include to extend the models to cover additional concepts, like the complex genetic variants, and to continue the ongoing review process in the international CKM. Further, additional model reviews at the Norwegian and German repository instances are already planned, and more will be organized in due time.

6. Acknowledgements

The authors from CRS4 dedicate this work to the memory of Gianluigi Zanetti, whose legacy continues to inspire. This work has been partially supported by the European Joint Programme on Rare Disease (grant agreement N. 825575).

Abstract. Traditionally, health data management has been EMR-based and mostly handled by health care providers. Mechanisms are needed to give patients more control over their health conditions. Personal Health Libraries (PHLs) provide a single point of secure access to patients' digital health information that can help empower patients to make better-informed decisions about their health care. This paper reports a work-in-progress on leveraging tools and methods from artificial intelligence and knowledge representation to build a private, decentralized PHL that supports interoperability and, ultimately, true care integration. We demonstrate how a social application querying such a decentralized PHL can deliver a tailored push notification intervention focused on improving self-care behaviors in diabetic adults from medically underserved communities.

Keywords. Personal health library, digital health, privacy, interoperability.

1. Introduction

Currently, patients receive important digital health information in multiple settings and through different communication modalities. Emerging evidence indicates that patients are frustrated by the lack of EMR interoperability among these fragmented systems and platforms [3-8] and want to have an active role in managing their data [1, 2]. Improved interoperability and support for patient-provider communication has the potential to improve patient satisfaction and, evidence suggests, could even help detect and prevent medical errors [8]. Table 1 summarizes some critical requirements of PHL from the patient perspective identified in the literature [1-8]. In digital health management, a health state is a digital representation of the state of someone's health at a point in time, including their medications, test results, exercises, diets, insurance claims, vaccines, allergies, appointments, and their outcomes. Such data come from diverse sources, including health care organizations, government agencies, and clinicians. It can also include digital health information from mass media and social networks. Health data also comes in different formats, including EMRs, family histories and genealogies, data streams from activity trackers, personal genome sequences, articles, videos, and public datasets. Health states change over time as data is acquired through ongoing health-

¹ Corresponding Author, E-mail: ashabann@uthsc.edu.

related processes and events embedded within those processes. A health-related intervention is a process, which could either be therapeutic or preventive. For instance, an intervention for self-management of chronic diseases (e.g. diabetes) focused on promoting health behavior change to improve clinical outcomes is an example of a preventive intervention. In this paper, we describe a strategic implementation plan for a social application querying a decentralized PHL that can deliver a tailored push notification intervention focused on improving self-care behaviors in diabetic adults from under-served communities.

Table 1. Patient requirements (Req.) for a PHL.

Req.	Description
<i>Construction and Management (PODs)</i>	
R1.1 R1.2 R1.3	A mechanism to construct a PHL by bringing their data together in a trustworthy, usable, and useful library by gathering different types of knowledge into a single resource.
R2	Ability to manage the PHL by adding, editing, or removing resources
<i>Access Management and Privacy (PODs)</i>	
R3.1 R3.2	Ability to decide what types of data should be kept, and who has access to that data
<i>Knowledge Acquisition and Aggregation</i>	
R4.1 R4.2	Ability to seek health information from constantly changing public sources, enriched with new streams and types of data
R5	Ability to decide what types of data is important enough to collect, manage, and share
R6	Ability to participate by sharing their data with citizen science and research initiatives
<i>Usage (Applications)</i>	
R7.1 R7.2	Ability to search through the PHL using intelligent mapping for vocabulary used to describe resources in their profile.
R8	Ability to annotate their own results from participating in clinical trials to look for patterns
R9	Ability to receive alerts about new information related to topics covered in the PHL
R10	Ability to play an active role in staying healthy by monitoring their progress
R12	Ability to find and use information including text summarization, knowledge mapping.
R13	Ability to get digital assistance: personalized alerts, literacy aids, translations.

2. Method

We provide a solution for constructing and using a Personal Health Library (PHL) inspired by the Social Linked Data (Solid) framework [9]. Solid builds on the future vision of the decentralized Web by providing an infrastructure for separating data from applications that process that data. It provides users with true ownership of their data by storing it among several Personal Online Data stores (PODs) hosted wherever they

desire, and selectively authenticating applications to access and process specific resources within those PODs. The proposed Solid-based PHL manages distributed data storage in several PODs and enables interoperability between applications by reusing standard protocols, formats, and vocabularies, and by providing a common access RESTful API. Table 2 shows the main features supported by the proposed Solid-based framework.

Table 2. Features supported by the proposed Solid-based framework.

F _n	Description
F1	<i>Agents</i> : Solid defines standard vocabulary to describe the different entities that contribute to a user’s profile as Agents of different types (Person, Organization, Device, etc.)
F2	<i>WebID</i> : Each agent has a unique WebID, which links to a public RDF-based profile document that may link to other extended profiles. Extended profiles represent different user’s application profiles.
F3	<i>Web of Trust</i> : Extended profiles can be used to build a Web of trust using the FOAF vocabulary by allowing agents to link their profiles in a public or protected way.
F4	<i>Web of Resources</i> : Whether it is a person, an inbox, a document, an image, a notification, or a relationship, everything within a profile is represented as a resource.
F5	<i>Hierarchical resource representation</i> : Resources can be organized hierarchically in containers (directories), which allows for fine-grained access control lists (ACL). Solid uses the WAC Ontology.
F6	<i>Resource Management</i> : RDF, the model driving the Linked Data Platform (LDP), follows REST principles of identifying resources by URIs. Users manage resources via HTTP operations on their URIs. SPARQL endpoints enable complex multi-pod data retrieval via link-following SPARQL.
F7	<i>Linkability</i> : Resources stored in different PODs are represented following LDP recommendations. LDP enables agents to dereference resource URLs to reach a resource from another. Links within LDP are typed, which enables agents to explicitly state how their linked resources are related.
F8	<i>Live Notifications</i> : are implemented following the W3C LDN protocol and <i>ActivityStream Vocabulary</i> and enable users to interact with content on each other’s PODs and enable content owners to receive notifications in the appropriate <i>inbox</i> .
F9	<i>Portability and Interoperability</i> : The framework has a standard API that makes it easy for developers to write applications that allow users to use the same data in different applications instead of locking it inside different application data repositories
F10	<i>Security: Authentication</i> : The framework provides decentralized authentication, a global id space, and a global single sign-on through WebIDs. User has to register with an identity provider (their POD provider). The provider stores the users’ WebID profile document associated with a cryptographic key.
F11	<i>Privacy</i> : Access Control Lists (ACL). Solid uses the WAC Ontology to define read, write, edit, etc. permissions on resources. Since resources are hierarchical this allows for fine-grained access control. A patient can grant fine-grained access permissions to the different agents, ranging from a single person or a group to everyone. The patient can also have a list of trusted applications and control their access to the different resources in his/her POD.

3. Results

To showcase the proposed Solid-based PHL in action, we focus on one application scenario, featuring a preventive intervention from the chronic disease self-management domain:

Bob is an African American adult with diabetes equipped with a smart-phone that collects physiological data (e.g. step counts) in real-time. The social application on his smartphone queries his decentralized PHL to deliver tailored push notifications to support behavior change related to chronic disease self-care. Depending on sensor readings and other information in his PHL, the app provides personalized and tailored recommendations for healthy eating, physical activity, medication taking, and/or visiting healthcare providers. Alice is a cancer patient who is part of Bob's social network and Mary is his primary care physician.

We leverage the Solid infrastructure and the relevant linked data principles to assist Bob in constructing and managing his PHL as well as interacting with other collaborators in his health and social networks, through the Solid ecosystem.

First, Bob generates unique WebID to securely login to his profile document (Table 2, F2, F10), sets up his PODs, and keeps a list of vCard URIs of trusted (Table2, F3) agents and applications in his extended profile. He adds Alice and Mary as Person agents and he adds the monitoring app and his smartphone as *device* and *software* agents, respectively (Table2, F1). Bob is interested in *gathering* the latest blog posts about diabetes from a blogging app. He adds the app under the trusted apps section of his profile document. He grants each of the above agents a fine-grained access permission to the corresponding containers under his POD with the proper access mode (Table2, F11). He can set up a chatting *channel* of type LongChat about Diabetes as a resource under the Diabetes folder under his public folder (Table2, F4,F5,F6).

Alice and Mary can *subscribe* to the channel using their WebIDs and have message *notifications* pushed to their inboxes as resources with unique URIs and they can *collaborate* on assessing each other's messages. Bob can also *share* blog posts that he receives from the blogging app to Alice's inbox. Alice gets a notification in her inbox of the blog post (Table2, F8). She has several options to *interact* with the document, including replying to Bob, adding *annotations* to robustify links in the document by linking them to other concepts or sources of knowledge, and save either a copy of that document to her POD or a link to Bob's copy.

Resources generated by each of the three users is stored in their corresponding PODs, but can be linked to each other (Table2, F7). For example, message notifications get pushed by the messaging POD to the inboxes of the users who subscribed to the messaging app as resources with unique URIs. Assuming a message stored in Bob's profile is identified by <https://bob.solid/messages/diabetes/1234>, then Alice's comment at <https://alice.solid/comments/36756> links back to Bob's message by the *hasTarget* Link Type defined in the Web Annotation Ontology (www.w3.org/ns/oa).

4. Discussion and Future Work

This paper has shown how a social application querying such a decentralized PHL can securely access, exchange, and use PHLs and deliver personalized and tailored push notifications to support chronic disease self-care. In this paper we employed a Solid-

based framework to assist users in constructing their PHL by gathering different types of data, information, and knowledge into a single searchable resource. While there has been some effort to build similar systems, the novelty of the proposed approach lies in i) providing a decentralized, yet linked architecture; ii) supporting interoperability, portability, knowledge mapping, and reasoning by following protocol, format, and vocabulary standards; iii) building trust with patients by facilitating true ownership over their data, and appropriate reporting; and (4) giving them a fine-grained access control mechanisms.

Future work will focus on further implementation of an end-to-end framework of intelligent recommendation and digital assistance tools, including text summarization, knowledge mapping, and personalized resource suggestions. In achieving this goal, we will incorporate AI techniques and knowledge representation methods that have been successfully used in our previous works [10, 11, 12]. Other ongoing tasks will include setting up a clinical trial of the social application and recruiting participants to fully evaluate the application.

Abstract. Electronic glasses use advanced assistive technology that can improve function for persons with visual impairments. This paper presents work in progress in the SmartSight project, where existing versions of electronic glasses are adapted and tested for persons with the visual impairments; macular degeneration and retinitis pigmentosa. The project aims are to adapt and innovate electronic glasses for persons with impaired fields of vision and study the impact on the daily function and quality of life. In a pilot test of the electronic glasses, promising results were found that imply a big difference for persons with impaired vision. The outcome of the SmartSight project might change the clinical practise on treatment and rehabilitation of persons with impaired fields of vision, and on how the support services are organised.

Keywords. E-accessibility, Visual impairment, Augmented reality, E-glasses, Usability evaluation

1. Introduction

Two large patient groups have eye diseases that impair their fields of vision, inducing problems in everyday living and thus reduced function. Macular degeneration (MD) causes the central vision to deteriorate while the peripheral vision remains intact [1], see Figure 1 middle. One in ten older than 70 years of age have functional impairments due to MD [2]. In retinitis pigmentosa (RD) central and peripheral fields of vision are impaired, giving a “tunnel vision” for persons affected [3], see Figure 1 right. This is problematic for orientation and implies more impaired vision in dark surroundings [4]. The total prevalence of all different forms of retinitis pigmentosa is variably reported (one case for each 2500 - 7000 persons), but represents one of the most common causes of blindness or severe low-vision in people 20 to 60 years old [5].

¹ Corresponding author, e-mail: berglind.smaradottir@uia.no

Figure 1. The field of vision for normal vision (left), macular degeneration (middle) and retinitis pigmentosa (right).

In this context, the SmartSight project (*Electronic glasses to improve function for persons with impaired fields of vision*) addresses research gaps connected to clinical studies of eHealth assistive technology aiming to improve function and quality of life for persons with impaired fields of vision. The software in existing technology of electronic glasses (eGlasses) will be adapted to improve function and coping for persons with impaired fields of vision. The effects of using eGlasses will be measured and tested for persons with macular degeneration and retinitis pigmentosa.

The main hypotheses are that use of electronic glasses will have beneficial effects on individual, organisational and societal levels. The research questions (RQs) stated for the SmartSight project:

RQ1: How can the functionality of existing eGlasses products be adapted to improve function and coping for persons with impaired fields of vision?

RQ2: What benefits and effects of using such customised products can be measured for individuals and for the society?

RQ3: What are the user experiences with such customised products?

2. Methodology

To address the user experiences, a mixed-methods research approach will be applied to evaluate the usefulness and user satisfaction with the eGlasses [6][7]. Initially, pilot tests will be made. User evaluations led by a cross-disciplinary research team, will be performed in a usability laboratory together with persons affected by macular degeneration and retinitis pigmentosa, followed by user satisfaction questionnaires and qualitative interviews [8]. By this systematic approach, real end-users get the opportunity to share their user experiences regarding the eGlasses and the results will be used for iterative refinements of the eGlasses. For each iteration in the technical development, 4- 6 test participants evaluate the functionality and usability of the eGlasses. All laboratory tests will be video-recorded for analysis purposes [9][10].

To evaluate the long-term experiences; a 6-12 months long field study will be made with 10-12 participants using a high-fidelity prototype of eGlasses. During the study, there will be regular contacts between the research team and the test participants for evaluating impacts on fields of vision and daily life. Recruitment of test participants is made in close collaboration with The Norwegian Association of the Blind and Partially Sighted [11], the Eye Clinic at Sørlandet Hospital Trust [12] and The National Centre for Optics, Vision and Eye Care, University of South-Eastern Norway [13].

3. Results

The SmartSight project is in an early study phase. A workshop was organised together with The Norwegian Association of the Blind and Partially Sighted, where pilot tests of eGlasses were made. The eGlasses had mounted cameras, and modified pictures from the cameras were projected in the glasses.

Figure 2. The pilot test of different types of eGlasses. Photo: Mona Hauglid.

The tests showed promising results using unmodified eGlasses that may imply great differences for persons with retinitis pigmentosa [14][15], see Figure 3. Unmodified eGlasses did not give any benefit for persons with macular degeneration, but the modified versions are promising, see Figure 4.

Figure 3. A model of principle function of the eGlasses for retinitis pigmentosa.

Figure 4. A model of principle function of the eGlasses for macular degeneration.

4. Conclusion

The main contributions of the SmartSight study lie in the adaption and innovation of existing eGlasses technology, a detailed analysis of their usefulness, and user experiences from persons with visual impairments caused by macular degeneration and retinitis pigmentosa. These outcomes might change the clinical practise on examination and rehabilitation for persons with impaired field of vision, and improve quality of life by increasing employability and participation in social life. The outcomes might also have impact on the organisation of support services connected to this area of concern.

4.1 Acknowledgement

Thanks to The Norwegian Association of the Blind and Partially Sighted and to the persons that voluntarily participated in the pilot test. This study was funded by Research Grant no. 16/00528-27 of December 21st, 2016, from the South-Eastern Regional Health Authority in Norway.

Three-Dimensional Volumetric Renal Reconstruction Based on Geometrical Coefficients

Tomasz LES^{a,1}, Tomasz MARKIEWICZ^{a,b}, Mirosław DZIEKIEWICZ^b and
Malgorzata LORENT^b

^aWarsaw University of Technology, Warsaw, Poland

^bMilitary Institute of Medicine, Warsaw, Poland

Abstract. The article presents an innovative method of 3D computer tomography (CT) image reconstruction of kidney. Diagnosis based on CT scanning allows to obtain projections of multi-dimensional object, made from different directions in order to create cross-sectional (2D) slices. Standard techniques for identifying kidneys in CT images analyze each 2D slice separately. It causes different reconstruction accuracy for the same object at its different heights. This is the main problem of a machine-learning systems. Reconstruction error of end-slices of the kidney model is often greater than the error of the kidney's middle part. The main idea of the technique presented in this paper is to analyze the largest coherent 3D spatial-areas. This technique allows to increase the accuracy of kidney detection as well as to decrease the FP (false positive) error. An additional advantage of the developed algorithm is the possibility of obtaining a precise model representing the 3D view of an entire kidney.

Keywords. renal, reconstruction, geometrical-coefficients

1. Introduction

Quick and effective diagnosis of kidney diseases is possible by usage of a precise X-ray imaging. Increasingly more accurate projection, combined with novel methods of an automatic segmentation and visualization of the organs, e.g. kidneys, allows a better diagnosis of the disease and also a selection of a more appropriate treatment. An accurate kidney detection is particularly important for the cancer diagnosis. According to WHO Cancer Mortality Database, 400 000 new cases were diagnosed in 2018 [1]. Kidney cancer is the ninth most common cancer among men and 14th among women. The highest incidence rate covers the countries of Central and Eastern Europe (Belarus, the Czech Republic) and the Baltic States (Lithuania, Latvia and Estonia).

Current techniques for diagnosis of kidney diseases are based on CT image analysis, followed by manual or semi-automatic segmentation in order to detect the kidney area. Although, a 3D reconstruction of the kidney is often used in diagnosis for a better visualization. Modern CT scanners generate large number of scans with high density. This is an advantage, however, it causes also that the manual analysis,

¹ Corresponding Author, Warsaw University of Technology, Koszykowa 75, 00-662 Warsaw, Poland;
E-mail: lest@ee.pw.edu.pl.

performed by specialists, of a large number of images, becomes time consuming and involves the risk of human error caused by, for example, tiredness. Therefore, there is a necessity to develop a new, more accurate and faster techniques for an automatic diagnosis and visualization of kidneys. Current kidney identification techniques are based on the analysis of each slice separately. The consequence is that the accuracy of recognition of an individual kidney contours on different slices can vary significantly. This is particularly important when analyzing the end-slices of a kidney where the accuracy of a detection is often worse than the accuracy of a kidney detection in the middle slices. This causes false positive error, difficult to decrease with standard techniques.

In this article, a novel volumetric technique of a renal reconstruction is presented, based on an analysis of geometrical coefficients for 3D kidney model. Renal contour detection is performed on all scans together unlike in many popular methods which analyses each slice separately. The final 3D model generated using our technique is also more precise than model using standard techniques.

2. Automatic renal segmentation technique

In this section we present a complete system of the 3D kidney reconstruction. The starting point of the algorithm is a set of n images encoded as gray-scale images, representing individual slices of renal. Input images can be obtained, e.g. using morphological operations [2,3], segmentation methods [4-6] or methods based on machine learning [7-9]. Regardless of the used method, the key task is to calculate the appropriate threshold for binarization final mask. In our experiment we used U-Net multilayer network model to obtain the input data: raw CTA images of dimensions of 512 x 512, frame size 48x48 (defined the input layer of U-Net), encoder depth equals 4 and convolution filter size equals 3. Other neural network parameters we applied: initial learning rate: 0.07, momentum 0.9 and LZ regularization 0.0002, number of epochs: 20 and minimal batch size: 256.

Output of the network frame classification is the gray-scale image. The value of each pixel $c = [x, y]$ equals the number of votes that the pixel c belongs to the renal area when the sequential frames are classified by the network.

It is difficult to calculate the optimal threshold value (t value) for a segmentation of renal area. Moreover, t value differs for different cases and also for each renal in one case. The main, novel contributions of this work include a method of calculating geometric coefficients for the entire 3D renal model, for different threshold levels. Following coefficients are calculated for each renal separately: fc - the circularity ratio (1) and fh - the compactness factor (2).

$$fc = \frac{A}{P} \quad (1),$$

$$fh = \frac{P^2}{A} \quad (2)$$

Directly measured parameters are denoted by the following symbols:

- A – real area of the renal
- P – perimeter of the renal

Finally, the p factor is calculated by the formula (3):

$$p = \frac{fc}{fh}$$

(3)

Next, the algorithm selected minimal p value and corresponding t value. Table 1 presents the dependence of the p value and t value, as well as of the fc and fh factors for one case.

Table 1. Dependence of the t , p , fc and fh factors for one case.

t	fc	fh	p	t	fc	fh	p
17	10147.06	7.92	1281.095	28	2063.42	12.03	171.474
20	9868.72	7.80	1265.137	29	2071.86	11.98	172.970
22	9756.89	7.71	1265.934	30	2102.20	11.86	177.223
23	2177.78	11.91	182.855	31	2116.63	11.79	179.543
24	1987.00	12.39	160.358	40	2302.47	11.02	209.019
25	1983.68	12.37	160.356	60	4774.24	5.88	812.425

Fig. 1 presents plot of minimal p value range in relation to t value.

Figure 1. Plot of minimal p value range in relation to t value.

The minimal p value is obtained for t range from 23 to 40. For these values the reconstruction is the most precise. Our method allows a simple selecting the minimum value of p (which is equal: 160.356 in this case) and an optimal threshold value t (equals 25 in this case). The more general analysis of other cases allows to observe that the optimal t value ranges from 20 to 50. This technique is applied for each renal separately. Fig. 2 presents the results of a complete reins reconstruction using t value equals: [22,25,60].

Figure 2. Complete reconstruction of reins for t value of: [22,25,60], for one patient.

In this case, the best reconstruction quality can be obtained for the threshold $t = 25$. This value was calculated automatically basing on coefficient factors fc , fh and p value.

A full diagram of a complete system for 3D reconstruction of the reins is shown in fig 3.

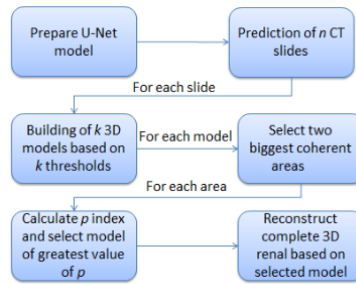

Figure 3. A full diagram of a complete system for 3D reconstruction of reins.

3. Test and results

In numerical experiments we have recognized 21 cases, each consisting of 60-250 slices. In total, 1335 CT images were tested. For each case, automatically, a complete 3D reconstruction of a renal was realized as well as the final binary masks for each individual slice were calculated. Each mask was compared to mask obtained by an expert from the Military Institute of Medicine and final Renal Sørensen-Dice coefficient was calculated. Detailed numerical results of recognition accuracy are presented in Table 2.

Table 2. The accuracy of renal area recognition for 21 cases.

Case	Accuracy	Case	Accuracy	Case	Accuracy
1	87.60	8	84.82	15	80.41
2	92.45	9	59.91	16	85.66
3	75.97	10	90.08	17	87.02
4	90.70	11	78.36	18	91.02
5	88.85	12	89.48	19	94.41
6	96.60	13	94.29	20	95.24
7	91.00	14	89.39	21	95.13
mean					87.54

Experimental results show the good performance of the proposed system. The main accuracy of kidney reconstruction equals 87.54%.

The results of renal boundary detection for exemplary slices were presented on fig 4. The green line represents the expert's result and the red line represents the system's result.

Figure 4. Results of renal boundary detection for exemplary slices. The green line represents the expert's outlines and the red line represents the system's results.

4. Conclusion

This paper presents a novel method of the 3D renal reconstruction. The presented technique allows to obtain a precise boundary of the reins in both three-dimensional

and two-dimensional projections. Our algorithm allows for calculating the optimal thresholding value for gray-scale images. An automatic selection of threshold is a difficult task due to the very high variability of the intensity of each slice. The existing techniques for visualizing the correlation of threshold values and reconstruction results use the roc curve. However, those techniques do not allow for automatic selecting of one optimal value. The proposed technique was tested using a set of data generated by the U-Net network, however, many other techniques generating gray-scale images (e.g. basing on morphological operations or segmentation methods), can be used in our solution. The main novel idea used in the presented system is to analyze geometric coefficients (circularity and compactness) as volumetric factors. The result of the coefficient calculation allows selecting optimal threshold value, binarization and final renal boundary recognition. In order to assess the quality of the proposed system, numerical tests were performed. Each mask was compared to a mask obtained by an expert from a medical institute. The numerical results of this verification have been presented and discussed in this paper. The measurable benefit of the presented system is a practical tool for visualization and evaluation of very significant cancerous change. Despite satisfactory research results, it is necessary to constantly develop new methods to support medical diagnostics in order to improve treatment results.

Abstract. The web portal Medfloss.org lists over 360 medical free/libre and open source software (MEDFLOSS) projects. These projects are described with the help of a self-developed nomenclature. Due to inconsistencies, the nomenclature shall be replaced by HITO, the Health IT Ontology. HITO is developed iteratively based on different use cases. This paper aims to describe methods and results of the second HITO use case in which HITO is extended to improve the description, retrieval and comparisons of MEDFLOSS projects on Medfloss.org. We use a mixed-methods approach to add concepts and relationships to describe MEDFLOSS precisely. The resulting HITO version stresses functional descriptions based on features and supported enterprise functions, rather than just describing technical characteristics. However, describing a larger number of MEDFLOSS projects requires the commitment of the community.

Keywords. Health Information Systems, Software, Semantics

1. Introduction

Medical free/libre and open source software (MEDFLOSS) is widely used in academia and in low-resource settings, but also in healthcare institutions of industrial countries such as the US and UK [1]. The web portal Medfloss.org gives an overview of 363 MEDFLOSS projects, 111 professional service providers and 436 publications dealing with MEDFLOSS [2]. The portal is provided in cooperation with the FLOSS working groups of the European Federation of Medical Informatics, the International Medical Informatics Association and the International Society for Telemedicine & eHealth. About 3.350 visitors consult the website every month.

To describe software projects, Medfloss.org uses a self-developed nomenclature describing software by categories such as “application type”, supported “enterprise functions” and “license”. Since the establishment of Medfloss.org in 2010, the uncontrolled growth of the nomenclature has led to inconsistencies such as misassignments of descriptors to characteristics (e.g. “Virtual Reality” is listed as

¹ Franziska Jahn, Leipzig University, Medical Faculty, Institute of Medical Informatics, Statistics and Epidemiology, Härtelstr. 16-18, 04107 Leipzig, E-mail: franziska.jahn@imise.uni-leipzig.de

enterprise function) and the use of synonyms and homonyms for the descriptions of MEDFLOSS projects.

The Austrian-German research project HITO aims at the development of a **Health IT Ontology** for the systematic description of application systems and software products used in healthcare [3]. Whereas software products are tailor-made or purchased pieces of software that can be installed on a computer system, application systems are already installed software products that are adapted to a certain organizational environment [4].

HITO is developed iteratively by means of five use cases that currently lack precise application system and software product descriptions. Each use case is intended to add new concepts and relationships to HITO. In the first use case, we developed HITO V1 in order to improve the retrieval of evaluation studies examining application systems in healthcare settings [5]. HITO V1 systematically describes evaluated application systems by features, user groups and organizational units.

In the second use case, HITO V1 is extended by concepts and relationships for the precise description of MEDFLOSS (HITO V2) to improve retrieval and comparisons of MEDFLOSS projects on Medfloss.org.

This paper aims to describe methods and results of developing HITO V2.

2. Methods

We used a mixed-methods approach to identify important categories for the description of MEDFLOSS. The methods described in sections 2.1 to 2.4 were applied in parallel.

2.1. Surveying the Medfloss.org portal operators

In semi-structured interviews, two of the Medfloss.org web portal operators were asked about their experiences with the current terminology used on Medfloss.org and their ideas for improvement. On a 4-point scale ranging from “unimportant” to “very important”, both rated 8 out of 11 categories of the current terminology (enterprise function, application type, status, license, standard, language, client type, and platform) as “important” or “very important” for the description of the projects. The categories “popularity”, “database” and “programming language/toolkit” were each rated “less important” and “important” by one of the interviewees. They pointed out that the importance of these categories also depends on the perspective of the MEDFLOSS portal user. While health professionals are interested in functional software descriptions, software developers are more interested in technical categories.

However, from their point of view, the terminology currently lacks possibilities to describe the functionalities and application types more precisely. Therefore, the integration of existing terminologies such as WHO’s classification of digital health interventions [6] should be considered.

2.2. Comparison of three terminologies for describing MEDFLOSS functionalities

During the first HITO use case, we identified existing health IT taxonomies and ontologies [5]. To describe MEDFLOSS functionalities, we selected three of these taxonomies, which cover a broad range of health enterprise functions or application

system types systems, for a deeper analysis: (1) The reference model for the domain layer of hospital information systems (RDHIS) provides a hierarchy of enterprise functions (e.g. “medical admission”, “execution of nursing procedures”) [7]. Although it is originally developed for hospitals, many of these enterprise functions also fit in other healthcare settings. (2) The textbook “Health Information“ includes a list of application system types (e.g. radiology information system, patient administration system) used in healthcare and tries to avoid conceptual overlappings [4]. (3) Varshney et al. systematically developed a taxonomy of healthcare applications consisting of eight application system types [8].

For 356 projects listed on Medfloss.org, we counted how many of them could be described by the three taxonomies’ classes. The RDHIS gained best results in this comparison (Table 1). 71 % of the MEDFLOSS projects could be described by it. Only 13 of the 68 RDHIS’ enterprise functions could not be used for any description. With the help of application system list and the taxonomy of healthcare applications, only 42 % and 29 % of the projects could be described, respectively.

Table 1. Comparison of three taxonomies to describe 356 projects listed on Medfloss.org

	(1) Reference model for the domain layer of HIS [7]	(2) Application system list [4]	(3) Taxonomy of healthcare applications [8]
Number of classes	68	16	8
Number of Medfloss projects assignable to classes (n=356)	253 (71%)	151 (42%)	105 (29%)

2.3. Analyzing the Architecture of a MEDFLOSS-based Laboratory Environment

The MI-Lab at Leipzig University is a small computerized hospital information system architecture built up from several MEDFLOSS components [9]. Its analysis reveals that MEDFLOSS products can be provided as parts of other MEDFLOSS products. The Bahmni software used as electronic medical record (EMR) system in MI-Lab is composed of four other MEDFLOSS products providing a laboratory information system (LIS), an enterprise resource planning system (ERP), a patient management system and a picture archiving and communication system (PACS).

2.4. MEDFLOSS Literature Review

In order to find important characteristics for the description of MEDFLOSS products, we conducted a snowball search starting from a review on MEDFLOSS publications [1] which was complemented by a Pubmed and Google Scholar search on open source software characteristics and comparisons. Four out of seven articles providing structured descriptions of MEDFLOSS [10–13] list characteristics that are worth to be considered as HITO classes. However, the use of different self-developed lists of features or functionalities in the articles demonstrates the lack of a consented or at least organized terminology, but also unclear borders between features (e.g. “templates”) and supported enterprise functions (e.g. “billing”). Most of the categories used by Medfloss.org (2.1) can also be found in the articles: license, database, platform, programming language, language. Further categories describing privacy, security, usability, performance, customizability, user and developer support issues should be considered for inclusion into HITO.

3. Results

Based on our mixed-methods approach, we made the following design decisions for HITO V2 and explain them referring to the well-documented Bahmni software [14]:

- (A) All categories for the description of MEDFLOSS used on Medfloss.org are integrated into HITO V2 as classes because of their importance rating (2.1) and their use in MEDFLOSS literature (2.4). For example, Bahmni uses the license “AGPL 3.0” and supports the platform “CentOS”.
- (B) Functionalities of software products are described by combinations of supported enterprise functions and features (2.2, 2.4), e.g., Bahmni supports the enterprise function “Patient Registration” for which it provides the features “Register patients with their demographics”, “Identification contact”, etc. In a further step, these citations of software descriptions can be linked to entries of established catalogues for enterprise functions (e.g. [6,7]), and features (e.g. [6]), respectively. The enterprise function “Patient Registration” can be linked to the RDHIS function “Administrative Patient Admission”, for example. See Figure 1 for the corresponding HITO classes and relationships.

Figure 1. HITO V2: Relationships between functions and features as UML class diagram. Every citation of a MEDFLOSS description can be linked to a “classified” entry of a catalogue.

- (C) The RDHIS is transformed into a reference model for the domain layer of health information systems which includes enterprise functions for specific diagnostics and therapies, mobile health, research and public health (2.2).
- (D) The class “Software product” is linked with itself by a “part of” relationship (2.3). Thus, the relationship “Open MRS is part of Bahmni” can be expressed. HITO V2 is available as Linked Open Data as RDF on <https://hitontology.eu> [3].

4. Discussion and Conclusion

Using a mixed-method approach, HITO could be extended by a variety of classes for the description of MEDFLOSS projects. Besides rather technical characteristics like platform or programming language, the precise description of software functionalities for medicine and health care plays an important role for the selection and comparison of MEDFLOSS. Thus, the domain-specific description abilities of HITO can be considered as one of its strengths and could, in the future, make it comparable to the EDAM ontology used in bioinformatics to describe operations and data [15]. However, due to the different terminologies for functionalities and application system types already in use, a unification of terms cannot be achieved in the short term. The HITO

project therefore integrates different existing terminologies for features and enterprise functions with the long-term goal of linking their terms.

Although a user searching for a specific software often relies on allegedly established terms for application system types (e.g. EHR, EMR, PACS, LIS), these terms are not clearly defined. For example, an “electronic health record (EHR) software” might be developed for the use in practices, hospitals or healthcare networks. It may be the electronic collection of patients’ documents or it may provide full medical process support. For this reason, HITO currently focuses on functional descriptions. After describing a large number of software products, clustering might help to improve definitions of application system types. However, coming to a huge amount of meaningful MEDFLOSS descriptions by HITO depends on good documentation of the software projects and the commitment of the community.

Abstract. Multimorbidity is a major problem for patients and health services. However, we still do not know much about the common trajectories of disease accumulation that patients follow. We apply a data-driven method to an electronic health record dataset (CPRD) to analyse and condense the main trajectories to multimorbidity into simple networks. This analysis has never been done specifically for multimorbidity trajectories and using primary care based electronic health records. We start the analysis by evaluating temporal correlations between diseases to determine which pairs of disease appear significantly in sequence. Then, we use patient trajectories together with the temporal correlations to build networks of disease accumulation. These networks are able to represent the main pathways that patients follow to acquire multiple chronic conditions. The first network that we find contains the common diseases that multimorbid patients suffer from and shows how diseases like diabetes, COPD, cancer and osteoporosis are crucial in the disease trajectories. The results we present can help better characterize multimorbid patients and highlight common combinations helping to focus treatment to prevent or delay multimorbidity progression.

Keywords. multimorbidity, electronic health records, disease trajectory, multiple disease progression model

1. Introduction

Multimorbidity (the coexistence of two or more chronic diseases in an individual) is a growing health and healthcare challenge. There is significant evidence showing that the prevalence of patients with multiple chronic conditions has increased over time [1]. Nevertheless, we still do not know the temporal dynamics of disease accumulation over time in the development of multimorbidity. In this paper we study which are the trajectories of disease accumulation that patients follow to become multimorbid. Understanding what are the characteristics of these trajectories can be helpful to better identify and predict the disease progression of patients. We adapt the methodology proposed by Jensen et al [2] and we apply it to primary care electronic health records (EHRs) instead of secondary care EHRs. If we want to study multimorbidity we need to use primary care data since most chronic condition are treated in general practice. However, it is challenging

Rheumatoid Arthritis (RA)	Stroke or TIA	Severe Mental Illness (SMI)

to work with primary care data because it is not standardized between countries and the disease coding system used in the UK cannot be directly mapped onto the ICD-10 coding system. We are the first to apply this methodology to find trajectories of chronic disease accumulation using this type of data.

2. Data

To perform the analysis we used the CPRD (*Clinical Practice Research Datalink*) dataset [3] that contains EHRs from general practices across the UK. Our study included 1.1 million English people aged 45 and over, followed up from 2001 to 2010. Since there is no clear definition of the chronic conditions that define multimorbid patients we combined 3 different approaches to decide which were the diseases of interest: a systematic literature review of the diseases included in multimorbidity studies, the NHS Quality and Outcomes Framework disease list and expert advice from primary-care clinicians and clinical epidemiologists. Our final list is shown in Table 1. The CALIBER platform [4] provided the data extracts and phenotyped the disease codes.

3. Methods

The method used is based on Jensen et al [2] and we adapted some aspects of the implementation to the specific circumstances of this analysis.

First, we computed the Relative Risk (RR) between all the pairs of diseases. The Relative Risk between disease A and B measures if A is a risk factor for B (i.e. a temporal correlation measure): $RR_{A \rightarrow B} = \frac{P(B_{t=T}=1|A_{t=0}=1)}{P(B_{t=T}=1|A_{t=0}=0)}$, where A_t and B_t are random variables of being diagnosed or not with diseases A and B at time t . We estimated 5-year RRs by matching each patient with $A_{t=0} = 1$ (exposed group) to N comparison groups where $A_{t=0} = 0$. The comparisons groups were matched at baseline by sex, age and deprivation index. We computed the P -values as the proportion of comparison groups where the count of cases with $B_{t=5} = 1$ is larger than in the exposed group. We selected all pairs $A \rightarrow B$ with $RR_{A \rightarrow B} > 1$ and P -value < 0.05 . In case of selecting both $A \rightarrow B$ and $B \rightarrow A$ we checked which direction was more significant. To evaluate the directionality we performed a Binomial test with the number of cases $N_{A \rightarrow B}$ and $N_{B \rightarrow A}$ in each direction. We kept at most one direction if it had P -value < 0.05 .

Once all pairs of relevant directions were obtained we went through the dataset to find patient trajectories formed only by these pairs. If a patient is diagnosed with $A \rightarrow B \rightarrow C \rightarrow D$ we considered that trajectory for our analysis if all the pairs $A \rightarrow B$, $B \rightarrow C$ and $C \rightarrow D$ are relevant. We only selected trajectories with at least 4 diagnosed conditions and with at least 5 patients going through that trajectory. Afterwards, we merged all these trajectories to form a network where each node represents a disease. Finally, we clustered the resulting network using the Markov Cluster Algorithm [5].

4. Results

We used RRs to measure the temporal correlation between the different diseases. To compute the RRs we used 1000 comparison groups for each exposed patient. In Figure 1 we show the significant 5-year RR between all pairs of diseases. From the 870 pairs of disease we find that 648 have $RR > 1$ and $P\text{-value} < 0.05$. There are 281 pairs of diseases (A, B) where $RR_{A \rightarrow B} > 1$ and $RR_{B \rightarrow A} > 1$ and the $P\text{-values}$ are under 0.05. Therefore, we checked for directionality to select the most significant directions of the two. After removing the less significant directed pairs we obtained 367 relevant directed pairs of diseases.

Figure 1. Relative Risks heatmap. The x-axis represents the baseline disease and the y-axis the follow-up disease. The x-axis and y-axis follow the same numerical index. The black dots indicate that $RR < 1$ or $P\text{-value} < 0.05$ so the relative risk is not significant. There are values with $RR > 10$ but for visualization purposes we have limited the colorbar range.

We searched disease trajectories from patients in the CPRD dataset formed exclusively by these significant pairs of diseases and with at least 4 diagnoses in the trajectory. Then, we merged all trajectories that have at least 5 patients going through them and we obtained a network of diseases where the diseases are the nodes and the edges are the transitions in the trajectories. We applied the Markov Clustering Algorithm [5] to the network and we obtain two clusters. The main cluster is shown in Figure 2 and contains 16 diseases. To visualize the second cluster in Figure 3 we added 3 disease long trajectories. There are some diseases that do not appear in any of the two clusters since they do not appear in 3 long patient trajectories formed by RR significant pairs. These

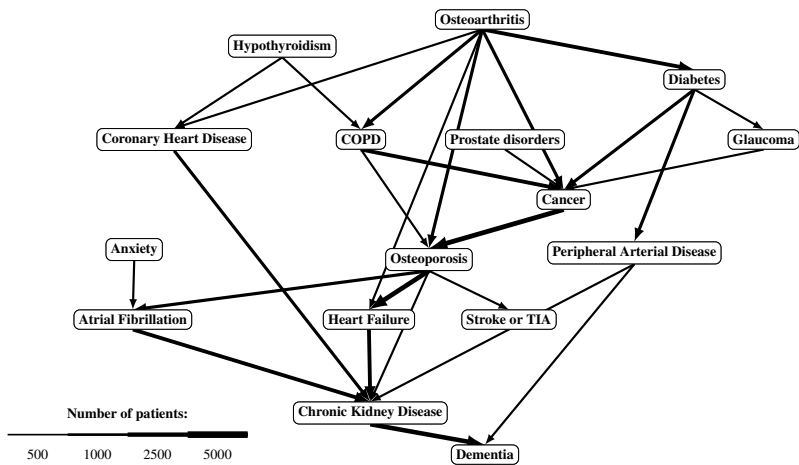

Figure 2. Main cluster of disease trajectories. The edge width represents the number of patients going through that diagnose sequence

Figure 3. Second cluster of disease trajectories or Depression cluster. The edge width represents the number of patients going through that diagnose sequence

two clusters describe the most common trajectories of chronic disease accumulation. The main cluster network was build using trajectories of 4 conditions. Consequently, there are disease trajectories that start in a node with incoming edges.

5. Discussion

In this analysis we used EHRs from primary care to investigate the sequence in which patients get multiple chronic conditions. When studying multimorbidity it is not clear which are the chronic conditions that need to be taken into account. Thus, we decided to focus on a relatively small but prevalent number of diseases to understand what are the most common trajectories that multimorbid patients follow. We started by computing the RRs between diseases to evaluate the temporal correlation between any pair of conditions. Previous studies have focused on studying RRs of specific pairs of diseases. However, we were able to directly estimate 648 RRs thanks to the large dataset used. Most RRs related to learning disabilities, multiple sclerosis and motor neurone disease were found not significant due to the small amount of diagnosed cases. It is not possible to compare directly these RRs to previous studies because the time frame and disease definition can vary. Nevertheless, we found similar estimates for multiple pairs like CKD and Dementia [6] or PAD and CHD [7].

The main cluster shown in Figure 2 condenses the most common trajectories to multimorbidity into a single network. We can see how diseases like cancer, COPD, dia-

betes and osteoporosis are central in the progression. We also can observe clinically well known trajectories like *Diabetes* → *PAD* → *Stroke* [7]. The second cluster in Figure 3 shows reasonably expected alcohol problems related trajectories with depression as the initiating disease. However, there are many other trajectories that the two clusters do not cover. A dataset with a longer follow up period would help improve the results since we would be able to observe more complete trajectories. Previous work have applied this methodology to Secondary Care data and ICD-10 codes [2]. However, secondary care data does not capture most of the long lasting chronic conditions that multimorbid patients suffer from.

We know that sex and deprivation index are key factors to understand multimorbid patterns [8]. Consequently, in the future we should focus on finding specific trajectory networks for different population subgroups.

6. Conclusion

We used a data driven method to obtain networks that describe the main trajectories that patients follow to become multimorbid. The application of this method to a primary care dataset like CPRD confirms some of the already know temporal correlations between diseases and detects longer less known disease sequences. However, this method does not capture all the complex patterns that multimorbid patients follow. A main limitation of the model is that it only uses a directionality between the pairs of diseases. In the future we should focus on detecting specific trajectory patterns for different populations subgroups.

This work was partially supported by the National Institute for Health Research Collaboration for Leadership in Applied Health Research and Care North Thames at Bart's Health NHS Trust. The views expressed in this article are those of the authors and not necessarily those of the NHS, the NIHR or the Department of Health and Social Care. The NIHR UCLH Biomedical Research Centre and EPSRC grant M020533/1 also supported this work.

Abstract. Social determinants of health (SDH) are a valuable source of health information which still are not fully utilized in the clinical space. Knowing that a certain patient has trouble finding transportation, has a potentially hazardous relationship with a family member or close relative, is currently unemployed, or various other social factors would allow providers to tailor treatment plans in a way to best help that patient. However, these SDH must be gathered, represented, and stored in a standardized way before they can be leveraged by informatics tools designed for health providers. This process of translating SDH to standardized clinical entities includes two main steps. The first is a collaborative effort to establish an ontology of medical terminology codes (i.e., ICD, SNOMED, LOINC, etc.) which can be used to uniformly represent SDH as coded concepts. The second is a collaborative effort to use the FHIR standard to create profiles and extensions which will allow FHIR resources to be used to store the coded SDH as clinical entities. Each of these steps has their own complexities that must be considered and accounted for in future efforts to create interoperable clinical informatics solutions which utilize SDH.

Keywords. Social determinants of health, FHIR, interoperability, translational informatics

1. Introduction

The World Health Organization (WHO) recommends “systematically addressing” social determinants of health (SDH) to improve the health of the population as a whole [1]. Although there are many medical schools which provide training regarding SDH [2], some research has noted that current training strategies which “focus on knowing rather than acting cannot effect the change which will reduce health inequity in a meaningful way [3]. One recent study developed five categories of activities which should be used in tandem to fully address social needs. There, the authors describe the need of

¹ Michael Watkins, Corresponding author, Biomedical Informatics, University of Utah, 421 Wakara Way, Salt Lake City, Utah 84108, USA; E- mail: michael.watkins@utah.edu

developing an interoperable digital infrastructure that can easily share data between healthcare and social care organizations. The study also showed *awareness* as being just the first step in addressing a social issue; the other four categories include *adjustment*, *assistance*, *alignment*, and *advocacy* [4].

However, despite their potential implications in health, SDH are not a commonly utilized data source in most clinical workflows. Healthcare providers are already collecting some of this data, although this collection often occurs in an inconsistent and unstructured way. A structured, standardized method of SDH data collection by providers could inform individualized treatment, improve care coordination, and allow for a better population-level understanding of social and health equity for policy makers and healthcare system administrators. There are a few current informatics solutions that have sought to utilize SDH within the healthcare provider's office [5-6]. However, these are specific use-cases implemented among relatively small populations. In order to increase the population sizes included in such studies, interoperability must be a priority. This will allow cross-site deployment and wider-scale evaluation.

2. Background

The translation of SDH to standardized clinical entities is a complicated process due to the sheer number of stakeholders (i.e., government organizations, hospital systems, providers, clinical vocabulary creators, etc.) involved in the standardization of any clinical process. However, the informatics solutions discussed here will provide a high-level overview of the domains that decision-makers in SDH clinical implementation projects require.

The WHO defines SDH as “the conditions in which people are born, grow, work, live, and age, and the wider set of forces and systems shaping the conditions of daily life [1].” Marmot et al. summarized the relation of SDH to health as follows: “The poorest people have high levels of illness and premature mortality—but poor health is not confined to those who are worst off. At all levels of income, health and illness follow a social gradient: the lower the socioeconomic position, the worse the health [3].” Commonly assessed SDH include employment status, education level, food security, access to health services, housing status, income, discrimination, and social support [7].

The HL7 Fast Healthcare Interoperable Resources (FHIR) Specification is an ongoing effort to create a clinical data standard which enables the kind of interoperability which is necessary to fully utilize informatics tools and solutions. It abstracts clinical data concepts into separate resources. These resources are given unique identifiers which are used to string them together in order to represent all possible clinical scenarios [8].

The branch of translational informatics is becoming an increasingly important aspect of health informatics research. As its name suggests, translational informatics is the process of translating data from its original form to another using informatics methods. In health informatics, this has enabled various data sources to be utilized by informatics solutions in the clinical space in a standardized way. A sampling of these data sources includes environmental sensors, wearable health tools, imaging devices, various -omics databases, and detailed drug pharmaceutical research resources. In each case, the data is not formatted for clinical use and must be translated to a common clinical data standard before it can be used for interoperable clinical informatics solutions. Because these data are so potentially useful in clinical use, translational informatics has been named as an important milestone in achieving a nationwide learning health system [9].

3. Methods

The first step in a translational informatics approach to standardize the clinical use of SDH is to establish a shared ontology which coordinates the representation of any single determinant as a coded concept. This ontology could draw from established clinical coding systems such as SNOMED CT or ICD-10. Creating an ontology would allow separate efforts to build on each other rather than duplicate work.

One study worked to create a compendium of structured, codable social risk factors from common medical terminologies (i.e., SNOMED, LOINC, and ICD) [10]. Subsequent efforts should build upon such efforts in a collaborative way to achieve a robust common clinical data set (CCDS) of SDH which can be formally adopted and used for future SDH clinical solutions. Coding the determinants is the first step to various downstream interventions which enhance the value of care provided to patients. Standardizing the coding process with a shared ontology will result in a uniform knowledge source.

While mapping SDH to clinical codes is an important first step, it must be coupled with a standardized approach to storing them as clinical data entities. The clinical standard most suited for this purpose is the HL7 FHIR specification which is comprised of detailed resources (e.g. Observation, Condition, etc...). These resources require concepts to be coded to medical terminologies. However, each of these base resources would need to be properly extended in order to ensure that different research efforts would be able to maintain interoperability. This extension process relies on FHIR profiles to be created and published which specify how the relevant resource would need to be adapted to accurately represent the specific new data type in question. These efforts are typically undertaken by coordinated working groups and result in a FHIR Implementation Guide (IG). The IG walks future implementers through the process of creating the specific resources and extensions.

4. Results and Discussion

As is the case in any informatics efforts, collaboration and standardization are the catalysts for real progress. The creation of a robust ontology of SDH medical terminology codes, and the utilization of the FHIR standard for the standardized clinical representation of SDH, is a vast undertaking. The following considerations are additional points which should be carefully considered by those who join this effort.

A working group, known as the Gravity Project, has recently been announced which will tackle the complex issue of specifying FHIR profiles and extensions which can be used to store SDH [11]. Their coordinated efforts to profile various SDH will result in an IG to assist in the standardized adoption of FHIR resources to represent SDH. SDH are varied and many FHIR profiles may already exist for certain determinants in connection with other clinical use-cases. Care should be taken by researchers to ensure that existing work is built upon and only modified if necessary. FHIR can also provide important interoperability and standardization to the process of SDH collection. The FHIR Questionnaire resource is a versatile option for representing SDH-gathering questionnaires or question sets. It allows each question to be internally represented with a corresponding clinical code. SDH have historically been gathered through sets of questions which probe the patient's lifestyle and other aspects typically associated with SDH. Due to the nature of SDH data, its collection often requires patient self-reporting.

For example, although patient addresses are frequently used to infer socio-economic standing from census tracts, ZIP codes, and other community area designations, this method is dependent on survey and census material which is often outdated [12]. To assume that the patient is poor, based on that address alone, would result in incomplete information for that determinant. Since most approaches to clinical SDH gathering will use direct questions to avoid that unreliability, using FHIR Questionnaire resources would allow questionnaires to be used across institutions.

Responses to these questionnaires can be represented as FHIR QuestionnaireResponse resources. While using a FHIR Questionnaire ensures that the SDH are captured as coded concepts, an additional step is necessary to create a profiled FHIR resource for each relevant question response. For example, although a positive response to question on smoking history would result in a corresponding coded SDH within the QuestionnaireResponse, an additional step would be required to create a profiled FHIR Observation resource to represent that information. An informaticist querying for information on that patient's smoking history will be guided by the smoking status profile and will look for that corresponding resource, not for an obscure response within a QuestionnaireResponse resource. Coding a patient's smoking history as a FHIR Observation resource would allow for the data to be queried by relevant CDS solutions for all subsequent patient interactions. This method also enables patient-level, system-level, or population-level analysis of both the questionnaires and the unique, standardized clinical concepts.

The creation of an SDH ontology will be further complicated by the fact that there is a high level of overlap between the common medical terminologies. Reconciling this overlap will require collaboration and iterative feedback from relevant stakeholders. However, it is a crucial first step because despite the clinical standardization available through FHIR, the value is lost if the underlying representation of SDH is ambiguous.

5. Conclusion

Clinical informatics is a field which continues to present new opportunities for utilizing nontraditional medical data sources. Combining clinical informatics and translational informatics can be a powerful source of innovation. SDH represent a vast and varied source of data which can have important implications for health services. However, in order to use SDH in a clinical setting, they must be translated to standardized clinical entities. Following our approach will require a collaborative effort to curate a robust SDH ontology and to create the necessary FHIR profiles and extensions to store SDH in the clinical space. As this work moves forward, it will allow health professionals to provide more informed care for their patients and will likely inform later efforts to create new interoperable clinical informatics solutions which use other nontraditional data sources.

Trodden Lanes or New Paths: Ballisto- and Seismocardiography Till Now

Nico JÄHNE-RADEN¹, Henrike GÜTSCHLEG and Michael MARSCHOLLEK

*Peter L. Reichertz Institute for Medical Informatics
of TU Braunschweig and Hannover Medical School, Germany*

Abstract. Ballisto- and seismocardiography (BCG/SCG) are methods of studying blood circulation and cardiac function by using the vibration measurements at the body surface, e.g. via accelerometers. The aim of this work is to show the current relevance of BCG/SCG for the target medical diagnostics. To reach this goal and to examine the relevance, an overall search for all BCG and SCG articles in the databases PubMed and IEEEExplore was first carried out ("ballistocardiography OR seismocardiography") for the years till 2019. The results of this literature study show, overall 425 papers for the years from 2003 till 2019, with BCG (317) as significantly stronger represented than SCG (120). The distribution of the included subjects shows that a smaller group ($n \leq 10$) of mostly healthy people is more common. Last but not least, we examined which sensors have been included in the articles since 2003, with the result that accelerometers, whether as self-developed prototypes or installed in smartphones, were used in slightly less than 50% of the articles found. The differences in the numbers of publications between BCG and SCG may also be due to the distinction's complexity between BCG, which is more intuitive, and SCG. Looking at the number and distribution of included subjects, it is noticeable that this is rather low and primarily healthy subjects are used. However, the publication increase indicates that we are at a threshold in this topic and actual benefit to medicine.

Keywords. Review, Ballistocardiography, Seismocardiography

1. Introduction

Ballisto- and seismocardiography (BCG/SCG) are alternative methods for studying blood circulation and cardiac function. In this case, the BCG maps the pulse wave with its parameters via recording at the extremities, the head (often large vessels) or structures adjacent to the body [1,2]. The SCG is more likely to be recorded at the thorax and shows direct functional parameters of the heart, such as valve closure [1–3]. These methods can be used to perform long-term cardiovascular or respiratory illnesses, as a support or extension of common techniques such as the ECG.

As early as 1877 J. W. Gordon published a treatise on "Certain Molar Movements of the Human Body Produced by the Circulation of the Blood" and thus a cornerstone of the BCG [4]. Over the years, BCG and other forms, such as SCG, have evolved. New feature parameters such as pulse transit time as a marker for blood pressure, have come into focus [3,5]. But what about today with these methods of cardiovascular diagnostics.

¹ Corresponding Author, Nico Jähne-Raden, Hannover Medical School, Carl-Neuberg-Straße 1, D-30625 Hanover, Germany; E-mail: Nico.Jaehne-Raden@plri.de.

Especially related to the improvement of technical devices, e.g. sensors, in terms of size, cost or performance, BCG/SCG could contribute to improve diagnostics and care.

The motivation of this work is not only to show the current relevance of BCG/SCG for the target medical diagnostics, but also current research content, such as subject properties or measuring system setups. The aim is to be able to make a statement if the technology of BCG/SCG is really increasing and gaining importance in the research field of medical diagnostic.

This includes the questions about the origin of articles since 2003, as well as the investigation of different research circumstances, such as the extent of the subjects, the set of subjects, used sensors.

2. Method

To answer these questions from the introduction and to examine the relevance of BCG/SCG, an overall search for all BCG and SCG articles in the databases PubMed and IEEEExplore was first carried out ("ballistocardiography OR seismocardiography"). For the investigation of the articles found, after elimination of duplicates, no limitations were made on the date of publication or the settings, e.g. Animal experiments or similar.

Figure 1. Amount of BCG/SCG papers over the years.

In Figure 1, the results of this overall search approach can be seen. We identified 2003 as the start of the renewed upswing in BCG/SCG research. With the adaptation of the literature search from May 2019 to the period beginning with the year 2003 up to the date of the search, the Prisma method for the literature search was continued [6].

After analyzing the paper found between 2003 and 2019, it was filtered for use in human medicine. In addition, review articles were excluded. With the inclusion of the found articles, the first author's seat, sensor technology, subject structure, number of subjects, general setting and the focus of the described work were extracted.

3. Results

The results of this literature study show, overall 425 papers over the years 2003 till 2019, that BCG is significantly stronger represented within the article than SCG (317/120).

Figure 2. Amount of publication of BCG (first) and SCG (second) sorted by country (only top 5).

However, a slight increase after 2007 is to be noted, as can be seen in Figure 2, a rather linear, marked increase in publication figures overall. For the SCG, the number of releases increased since 2011. In both cases, the US is the country with the most publications over the years (see Figure 2).

In addition to the general results on the distribution of the articles found by years and countries, with regard to the focus on BCG or SCG, it was further considered how the subjects in the respective publications composed. This includes not only the number of subjects, but also the composition of the groups of subjects, for example by the inclusion of healthy subjects or subjects with heart diseases (e.g., heart failure) or other disorders (e.g., sleep disorders). In Figure 3, we graphically analyzed the results of the subject analysis with regard to the articles found. The number of subjects in Figure 3 (left) is the distribution of the subjects used, considering the number of found items. The figure clearly shows an increase in the number of 1 to 5, 10 and 20 subjects.

Looking now at the distribution of the subjects included in the articles found, Figure 3 (top left), a clear majority of the inclusion of healthy or heart-healthy subjects is evident. Last not least, we examined which measurement technologies have been included in the articles since 2003, with the result that accelerometers, whether as self-developed

prototypes or installed in smartphones, were used in slightly less than 50 percent of the articles found. The others were pressure sensors and weighing scales. Looking at the general focus of the articles found, the majority has a medical focus, such as the analysis of signal parameters for diagnostics (total of 338 articles). Only 72 articles have a more technical focus, such as the usability of specific sensors

Figure 3. Number of used subjects in publications (left), type of used subjects (top right) and used sensing technology (bottom right).

4. Conclusion

Considering the listed results of this literature review on ballisto- and seismocardiography with a focus on the distribution to the focus area as well as the examination of the included subjects and the used sensor technology, an increasing number of publications starting from the year 2003 are shown. As a limitation of the review it has to be mentioned, that

we only used PubMed and IEEEExplore, which can be handled to mark a tendency and is not to be understood as complete. The publication slump which begins in the late 1970s can certainly be attributed to the development of image-based procedures, such as MRI and CT. The smaller peak in 2008 and the overall positive publication trend are certainly attributable to the smartphone as a new sensor system, as well as to technical developments (e.g., MEMS).

The differences in the numbers of publications between BCG and SCG may also be due to the complexity differences between the two methods. So, the BCG is a more intuitive method with less difficulty to identify features than the SCG. The increasing number of SCG publication figures can certainly be attributed to the increasingly sensitive sensor technology as well as the previous experience and findings in signal analysis. Moreover, Taebi et al. describe the challenges of the SCG, alone in the determination of the measuring position [7]. The distribution in the world shows the relevance of the topic worldwide, while North American, European and Asian research groups can be identified in the BCG area as well as in the SCG.

Looking now at the number and distribution of included subjects, it is noticeable that rather low and primarily healthy subjects are used. This is certainly due to the still early stage of BCG/SCG research. Of course, it is still kind of basic research, with meanwhile reaching consensus on basic signal BCG/SCG structures [see 2].

It is moreover interesting that beside the more obvious subject group of healthy and heart related subjects, the field of sleep issues are a noticeable field. For sure in a supine position while sleeping is near an optimal setup for BCG/SCG measurements.

But once again, SCG complexity shows itself (see also [7]). However, the increase in "diseased" subjects and in the number of papers in the recent years indicates that we are at a threshold in this topic and the actual benefit to the medicine, e.g. as diagnostic support, may be in the near future.

Abstract. Scarce literature exists as to the use of Petri Nets (PN) to model the dynamic evolution of health issues in a deterministic way. Starting from the HIN (Health Issue Network) approach, the paper aims at describing the suitability of PN in supporting the Case-Based Learning method for improving an educational simulation environment in which students can manage realistic clinical data related to the evolution of a patient's health state over time.

Keywords. Health Issue Network, Case-Based Learning, Electronic Health Record, Petri Nets, Medical education

1. Introduction

The increase of both life expectancy and incidence of chronic diseases and disabilities in western societies that goes under the name of “epidemiological transition” [1] implies that nowadays physicians must provide healthcare activities over time to patients with multiple chronic diseases and, eventually, with an acute concomitant condition. Unfortunately, the concept of time is not present in current models of clinical reasoning [2-4], as they focus on the cognitive process of making a diagnosis and do not address the problem of how medical conditions evolve over time in a patient's clinical history, and/or how each condition interferes with the evolution of the other co-existing conditions. Case-Based Learning (CBL) is one of the most effective methods for teaching/learning clinical reasoning [5]. CBL has been successfully implemented through computer-based simulations [6], but these “virtual patients” are generally acute cases rarely described under the perspective of health evolution over time. Although the clinical question “What is the diagnosis in this patient?” remains pivotal, our aim was to develop the ability to answer to three other important questions, that is: starting from the available information on a patient in his/her present state (i.e.

¹ Fabrizio L. Ricci, IRPPS CNR, via Palestro, 32 – 00185 – Rome, Italy; E-mail: f.ricci@irpps.cnr.it

given a specific pathophysiology and treatment), (1) how health conditions may evolve in the future given the present patient's health status? (2) which past health conditions have possibly evolved in the present health status? (3) which health conditions have influenced the evolution of other health issues?

The HIN (Health Issue Network) approach was introduced [7] to improve CBL in a simulation environment for medical education. HIN allows: (i) reconstructing the implicit knowledge that lies behind and origins the physician's way of thinking, turning it into an explicit knowledge that makes possible to extract real clinical cases from Electronic Health Records; (ii) formalizing the description of an evolution path of a health issue of a person, through the implementation of the Petri Nets (PN) formalism [8], which is capable of translating HIN's key concepts in a graphical language. In HIN the PN marking represents the health status of a person, which evolves from one issue to another: each place node can only contain one token at a time. The transition from a HI (place node of the PN) occurs via a well-defined evolution (transition node of the PN) – PNs are bipartite graphs. Moreover, HIN model is a P/T safe net [8]. More details on the HIN model can be found in [7].

The present work investigates more in depth how Petri Nets, and therefore the HIN model, are an accurate way to represent the evolution of a patient's health state over time. The article summarizes the main features of the HIN model, discusses why PNs are suitable as a formal model underlying the HIN model and highlights the added value of HIN project.

2. Basic concepts of Health Issue Network

The guiding idea of HIN is a network of clinical problems as a basis for modeling a person's medical history. Each episode of care starts with an initial clinical problem (e.g. a symptom) and is described by its evolution together with the healthcare activities that make up the care path implemented to solve the original issue. The HIN model is characterized by two key concepts underlying the evolution of a health state:

(i) *health issue* (HI), that is any problem related to a patient's health (diagnosis, diagnostic hypothesis, symptom, sign, condition or risk factor, iatrogenic problem, general class of problems) [9], and; (ii) *evolution*, that is any change in a HI through which the patient moves from one health state to another. Five fundamental evolutions have been identified: *examining in-depth*, *worsening*, *complication*, *recurrence* and *improvement*. A HI can evolve for its own dynamics and/or – if more than one HIs occur in the same patient – be influenced by other HIs in its evolution. Both evolutions and influences are intended as probabilistic events, but in the real history of a patient, a HI evolution has occurred or not: alternative paths (evolutions in conflict) do not exist.

3. The choice of Petri Nets

In order to represent the evolution path of a person's health state, the choice of the Petri Nets formalism is based on the characteristics of the evolution path, as these well match with the properties of the PNs. Moreover, PNs allow to reduce the complexity of real clinical cases of patients with chronic multimorbidity into a rather simple mathematical model, which allows a representation of cases suitable for an educational environment, in particular: realistic as to its ability to reproduce the concepts of

evolution of HIs and influence between HIs; customizable according different learning outcomes. Here following are some of the properties of PN related to their use in a HIN-based simulation environment to represent clinically meaningful situations:

the PN is a *linear system* – the aim of the HIN approach is to extract real cases from medical records and let the students carry out exercises based on real/realistic data. The learning outcome is the ability to identify the HI evolutions that really occurred. A patient's clinical history is the “sum” of the evolutions of each HI and, at any given time, the patient’s health state is the “set” of the active HIs. The evolution over time of a patient's health state can then be represented as a linear system composed by a series of defined states. For example: in a patient with chronic pulmonary disease (COPD) and initial prostatic hypertrophy (BPH) these co-existing HIs make up the initial health state and the clinical history is composed by all the evolutions of these HIs. PNs represent a series of transitions in a deterministic manner. Moreover, in PNs the effect of a “sum” of input perturbations is equal to the “sum” of the effects produced by each individual perturbation, with the possibility of breaking up a linear problem;

the PN is a *discrete distributed system* – not all HIs are connected to each other: this implies that the evolution of a patient’s health state actually comprises parts (subnets) that can be independent from each other. In the above example, the BPH can worsen and produce the need for surgery without any influence on COPD. A PN – as well as the system of the evolving health states;

the PN (as evolution of a patient's health state) is an *asynchronous system* – the evolution concerns one HI at a time and not more HIs together. Since each health state can be interpreted as sum of several partial and independent subnets, an evolution only influences a part of the overall state; the firing of an evolution at a time preserves the locality of evolution of HIN diagram: two unrelated evolutions “never occur at the same time”. In the above example, surgery makes the HI BPH evolve into “operated BPH”. Because of the process of care (surgery) the HI COPD may evolve in “acute respiratory failure”. If the patient has another unrelated HI (for example a symptomatic uncomplicated diverticular disease), this can evolve or not, but in any case, its evolution is recorded in a different time than the other ones;

a PN is a *system without memory* – when an evolution takes place, a new health state must be assessed to envisage potential health evolutions: new possible evolutions may have been enabled and some others disabled; the identification of the new potential evolutions doesn’t depend on how the new health state has been reached. Furthermore, for the educational purposes of HIN, the input to every single evolution of an HI is made up of all the HIs that make the firing of that evolution possible. In the above example, in managing the patient with a present state of BPH and COPD, a physician can only envisage through what series of evolutions the patient got to his present state. The set of previous evolutions are summarized in the actual state but cannot be detailed or inferred in any way.

Table 1. The correspondence between evolution for a patient's health state and for Petri Nets

Evolution of a patient's health state	Petri Net
Health Issue	Place
Evolution	Transition
Evolution path of a Health issue	Firing sequence
Health state	Marking
Clinical history	Reachability graph

Tab.1 shows the kernel of the correspondence between the concepts of the evolution for a patient’s health state and those for a PN system.

4. Results: the use of Petri net in the simulation environment

The HIN method also deploys the computational properties of PN_s. The three previously reported clinical questions can be solved in terms of the PN property of reachability [8]. These questions can be expressed as: (i) which HIs are achieved starting from a specific health state? (ii) which HIs are needed to reach a specific HI? (iii) what link exists between two identified HIs? Example: the learning outcome is the management of a patient with chronic co-morbidities (cardiac and renal failure) undergoing abdominal surgery for cancer and developing complications. The left box of fig. 1 shows the PN that represents the prototypical clinical condition, while the right box shows the HIN of a real case, selected from a database of medical record according to the selection criteria derived from the learning outcome. The real case has much more details and possibly slightly different paths of evolution.

Figure 1. An example of HIN diagrams

Examples of the above questions (right box of fig. 1) are the following: (i) which HIs are achieved starting from the health state {D', C, A'?} (ii) which HIs are needed to reach the HI C'? (iii) what link exists between the HIs C' and A'? In modelling a health state as a set of HIs, and therefore as a marking in the HIN model, PN_s allow solving these clinical questions by means of the reachability graph and of a firing sequence. Another use of PN_s is to measure the “distance²” between two HIN diagrams. This problem is solved via a rewriting of a PN (e.g. deleting a place-HI or a transition-

² We indicate with the term *distance* the difference in terms of places, transitions and edges, besides the possibility that the two diagrams can become equal after their rewriting.

evolution, or an edge). The analysis of graph distance is useful in the following scenarios:

- Choice of the real case – how far is the HIN diagram of a real case from the HIN diagram of the condition in the learning outcome? In the example of Fig. 1 the “distance” was analyzed between the HIN diagram for a didactic goal, and the HIN diagram of a real case (Mario).
- Given a set of HIs (without the related evolutions) with an indication of the initial and final health states, the learner is asked to envisage the possible evolutions of the health state, i.e. to draw the evolutions and influences and link them to the related HIs: how different will be the resulting HIN diagram drawn by the learner from the HIN diagram drawn by the teacher as correct solution of the exercise?

5. Discussion and Conclusions

Scarce literature exists as to the use of modelling tools for representing the evolution of a health issue. A number of papers describe modelling tools for developing workflows [10], protocols [11], or guidelines [12], but in all these cases the focus is on a flow of clinical activities planned and executed so as to accomplish specific tasks, or to work out clinical issues. No mention is made for what concerns the way activities can change the health state, or how this evolves over time. From an educational point of view as well, few works have been produced to develop educational models and tools for the competence of clinical management of chronic and multimorbidity conditions. Basically, the indications are about practical training and the use of virtual cases, which are not based on a sound theoretical model [13]. The HIN project is developing an integrated environment of theoretically based technical solutions to design, implement and assess the simulation of clinical cases of chronic and multimorbidity patients [7].

Using Big Data Analytics to Identify Dentists with Frequent Future Malpractice Claims

Wanting CUI^{1a}, Joseph FINKELSTEIN^a

^a*Icahn School of Medicine at Mount Sinai, New York, NY, USA*

Abstract. Healthcare spending has been growing at an increasing rate in the US, due in part to medical malpractice costs. Dental malpractice is an area that has not been studied in depth. Using National Practitioner Data Bank (NPDB), we explored the extent of dental malpractice claims and sought to construct a predictive model that can help us identify dental practitioners at risk of performing medical malpractice. Over 1,500 dental malpractice claims were reported annually, and over \$1.7 billion being paid out by medical malpractice insurers over the past 15 years. Majority of claims resulted in minor injuries, and the number of major injury claims increased over years. In prediction, we randomly split the data into train (75%) and test (25%) datasets. We trained and tuned models using 5-fold cross validation on the training set. Then, we fitted the model on the test data for performance measures. We used Logistic Regression, Random Forest (RF) and XGBoost and tuned the hyperparameters of models accordingly through grid search and cross validation. XGBoost was the best machine learning model to predict the risk of dentists having several malpractice reports. The best performing model had an accuracy of 72.8% with 30.6% F1 score. The NPDB database is a valuable dataset to study dental malpractice claims. Further analysis of information extracted from this dataset is warranted.

Keywords. Data Science, Big Data Analytics, Machine Learning, Predictive Model

1. Introduction

The United States currently ranks highest in health care spending among the developed nations of the world. In 2017, health care spending was \$3.5 trillion in total, which accounted for a 17.9% share of the nation's GDP. It has also increased over 50% in the past 10 years, compared to \$2.3 trillion in 2007 [1]. One of the reasons for the increasing cost of health care is defensive medicine. Defensive medicine refers to physicians prescribe diagnostic test or medical treatment that depart from normal medical practice as a safeguard from litigation [2]. According to a recent study, there is a statistically significant correlation between specialists concerns regarding potential medico-legal disputes and the choice of defensive medical procedures [3].

Although the number of malpractice claims has decreased since 2001, they are still very common in the United States. According to a 2016 Benchmark Survey, a third of

¹ Wanting Cui, Icahn School of Medicine at Mount Sinai, 1770 Madison Ave, New York, NY, USA, 10035, E-mail: wanting.cui@mssm.edu

physicians have been sued at least once in their career [4]. In addition, the average costs of malpractice cases have increased year over year. The malpractice insurance premiums have also increased accordingly, due to the high cost of malpractice claims. As a result, physicians' incomes may be affected by the rising cost of doing business as well.

While physicians' (MD, DO) malpractice cases have been frequently studied in recent years, there is little study on dental malpractice disputes and predictive models on future prevention are rarely constructed [5, 6]. In this article, using data from the National Practitioner Data Bank, we reported findings concerning the distribution of dental malpractices and the extent of dental malpractice risk. By studying malpractice, we hope to mitigate the high insurance premiums caused by the prevalence of malpractice claims. Our objectives were to review recent trends in dental malpractices, based on cost, number of claims, severity of injuries, physicians' and plaintiffs' information; and to create machine learning models predicting dentists with higher risk of frequent malpractices based on their first malpractice claim.

2. Method

2.1. Dataset

The dataset comes from National Practitioner Data Bank's (NPDB) Public Used Data File [7]. National Practitioner Data Bank, started in 1990, is a database that contains information related to the professional competence and conduct of physicians, dentists, and other health care practitioners. We accessed the data in 2019, so it included reports received from September 1, 1990 through December 31, 2018.

This analysis studied dental malpractice reports aiming to find important factors and to identify possible practitioners who could have repeat acts of malpractice in the future based on characteristics of their first offence. Due to several new variables added since January 31, 2004, and an average 4-year-gap between an incident and its payment, a 10-year-period (2005 – 2014), based on the report filing year (ORIGYEAR) was used in this study. In addition, only dentists (LICNFELD: 30) and dental residents (LICNFELD: 35) were included in this study. Records with missing data were deleted. Furthermore, only the first malpractice report of each practitioner was kept.

2.2. Variable Selection

Columns that are irrelevant to malpractice, such as Adverse Action Classification, Basis for Action, etc., were deleted from the dataset. After adjusting for inflation based on CPI-U for the U.S. City Average for All Items from the Bureau of Labor Statistics, we replaced Payment (PAYMENT) and Total Payment (TOTALPMT) by PAYMENT_ADJ and TOTALPMT_ADJ correspondingly. According to guidelines, we created a new variable 'STATE', which equals Work State if a work state value was reported and Home State if no work state was reported [7]. Since, for most practitioners, their License States (LICNSTAT) and their work States (STATE) are identical, we created a new binary variable State Difference (STATEDIFF), which is 1 if license state is different from state, and 0 otherwise. We counted the occurrences of each LICNSTAT, weighed against population of that state and rescaled those values to between 0.0001 and 0.9999. This information was stored in variable

'STATWEGHT_ADJ'. Similar to States, we created a new variable Payment Difference (PAYDIFF) to track the difference between payment and total payment. In addition, we created a variable Years of Experience (YREXP), for years between Graduation (GRAD) and Year of Act or Omission 1 (MALYEAR1). We also added variable Duration for years between MALYEAR1 and Year of Original Report processed (ORIGYEAR). A binary prediction variable 'RISK' was created based on the number of malpractice reports a practitioner had. The risk is 0 for a practitioner with only one malpractice report on record and the risk is 1 if a practitioner has more than one malpractice reports.

2.3. Statistical Methods

In variable analysis, we calculated summary statistics, such as mean, median and quantiles of continuous variables using standard methods. For those variables with skewed distribution, the Mann-Whitney test was performed to compare the difference between two risk levels. For variables with normal distribution, a two sample t-test was used. In addition, Pearson's Chi-Square test was used to identify differences between some categorical variables against the two risk levels.

In prediction, we randomly split the data into train (75%) and test (25%) datasets. We trained and tuned models using 5-fold cross validation on the training set. Then, we fitted the model on the test data for performance measures. We used Logistic Regression, Random Forest (RF) and XGBoost and tuned the hyperparameters of models accordingly through grid search and cross validation. Due to imbalanced data, we experimented with up sampling, down sampling and Synthetic Minority Over-sampling Technique (SMOTE).

All analyses were performed in RStudio (R version 3.5.3). All tests were two-sided, with $p < 0.05$ being considered statistically significant.

3. Results

3.1. Variable Analysis

Between 2005 and 2014, there were over 9,000 new dental practitioners who had their first malpractice cases reported. Of those practitioners, 7,494 (83.22%) of them were identified as risk free for multiple malpractices in the near future (Risk 0), and 1,511 (16.78%) of them were identified as at risk of multiple malpractices in the near future (Risk 1). Improper performance was the primary type of complaint.

Despite some fluctuations, the total number of malpractice reports generally decreased from 2005 to 2014. There were over 1,000 cases in 2005; this decreased to 857 cases in 2014 (Figure 1A). Although the number of cases decreased throughout the ten years being studied, mean payment amount after adjusting for inflation (PAYMENT_ADJ) increased for both risk free and at risk practitioners. This suggests that the cost of malpractice increased every year (Figure 1B). In addition, mean payment amount (Risk 0 = \$70,360; Risk 1 = \$105,660) and median payment amount (Risk 0 = \$22,436; Risk 1 = \$29,570) for at risk cases were higher than those for risk free cases (p value < 0.001). Average years of experience (YREXP) for the risk free group (mean = 24.17) was also significantly higher ($P < 0.001$) than that of the at risk group (mean = 22.96). Most practitioners have their first claim in their 40s.

Furthermore, there was a significant difference in the duration (DURATION) of each dispute between the two groups (p value < 0.001). The average duration of the risk free group was 3.27 years, in contrast to 3.93 years of the at risk group.

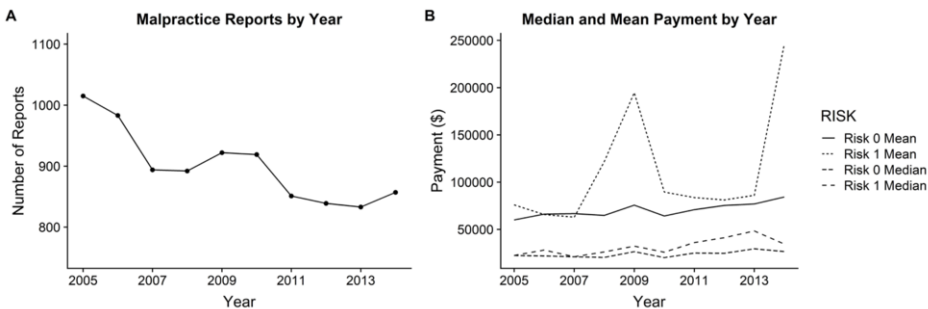

Figure 1. Malpractice reports trend.

There was no significant difference for different levels of outcome (OUTCOME) between the two groups (p value = 0.1159). While the amount of minor injuries decreased gradually from 2005 to 2014, the amount of major injuries increased. The amount of emotional injury and death remained constant. Moreover, there was no significant difference for gender of patients (PTGENDER) between groups (p value = 0.4). However, around two-third of the reports involved female patients and the proportion stayed consistent over the years.

3.2. Predictive Models

We used Logistic Regression as a baseline model. Prior to resampling the data, the logistic model categorized a significant amount of data to the risk free group, due to the imbalanced dataset. Thus, we experimented with up sampling, down sampling and SMOTE and compared the results. The result using Logistic Regression yielded a higher F1 score after resampling, increasing from 2.1% to 30.6%. However, the accuracy of the model decreased from over 80% to 60%. Thus, we would like to find a model that produced a high F1 score without the cost of accuracy. Both Logistic Regression and XGBoost produced relatively high F1 score. Up and down sampling methods also yielded better results than the SMOTE method (Table 1).

Considering XGBoost has a faster model training time and is a robust model which is less subject to overfitting, we decided to use XGBoost as our primary model. We fine-tuned hyper parameters of XGBoost using grid search. We also combined both up sampling and down sampling techniques using the ROSE package in an attempt to find balance between these two methods. The final model accuracy was 72.8% and F1 score was 30.6%.

Table 1. Predictive models results

Logistic Baseline	No Sampling (83.7%, 2.13%)		
	Down (Accu, F1)	Up (Accu, F1)	SMOTE (Accu, F1)
Logistic	(59.1%, 30.7%)	(60.6%, 30.9%)	(74.3%, 24.5%)
Random Forest	(57.7%, 30.6%)	(81.7%, 13.8%)	(81.4%, 11.8%)
XGBoost	(58.5%, 31.0%)	(61.6%, 30.0%)	(82.8%, 10.6%)
XGBoost (Best)	Up and Down Sampling (72.8%, 30.6%)		

4. Discussion

The final predictive model supports the previous discovery that payment amount, dentists' years of experience and length of disputes are major variables in determining whether a dentist is at risk of multiple malpractice cases in the near future. In addition, allegation type, dentists' working states and patient ages are also important factors for prediction.

A highly imbalanced dataset and categorical variables with multiple levels are the two main challenges for constructing predictive models. We employed different sampling techniques and used robust models that are suitable for categorical data to solve these issues. In future studies, we plan to optimize the probability threshold to overcome the imbalanced class problem. Furthermore, summary information of the dataset will be passed into the XGBoost model as additional features to improve model accuracy and F1 score.

5. Conclusion

In the past 15 years, over 1.7 Billion dollars of dental malpractice payments were awarded to patients. While the number of malpractices claims decreased through years, the payment amount per claim has increased. Practitioners' age was also an important variable. Dentists with more years of experience and older age were subjected to higher risk of having multiple malpractice cases in the near future. Additional standardized training should be provided to overcome improper performance issue.

XGBoost was the best machine learning model to predict the risk of dentists having several malpractice reports. The best performing model had an accuracy of 72.8% with 30.6% F1 score.

The NPDB database is a valuable dataset to study dental malpractice claims. Further analysis of information extracted from this dataset is warranted.

Using Business Intelligence Tools to Support Medical Validation of Laboratory Tests

Gian-Andrea DEGEN^{a,b}, Viola GÜNTHER, Jürgen HOLM^a, Thomas BÜRKLE^a, and Murat SARIYAR^{a,1}

^a*Bern University of Appl. Sciences, Dept. Medical Informatics, Switzerland*

^b*Institute for Clinical Chemistry, University Hospital Zurich, Switzerland*

Abstract. Modern clinical laboratories have to confirm that the procedures used for specific tests are reliable and valid. There are several sources of errors and interferences that can invalidate the results. Medical validation refers to the plausibility check of the test results. Implausible results indicate that something might went wrong with a sample retrieved from the patient, e.g., the blood sample got contaminated with another fluid, which requires re-examination. Here, we describe how an integrated R-based business intelligence (BI) tool can be developed that increase the efficiency of the medical validation at the Institute of Clinical Chemistry (ICC) of the University Hospital Zurich. A BI software environment allowed us to digitalize steps in the validation process that were manually done in Excel worksheets, e.g., importing the data, calculating percentiles, and producing graphical outputs.

Keywords. Clinical validation; delta check; extreme value analysis; business intelligence; R

1. Introduction

It is indispensable for modern clinical laboratories to confirm that the procedures and methods used for specific tests are reliable and valid. There are several sources of errors and interferences that can invalidate the results. One important distinction in this regard is between technical and medical sources [1,2]. The former one relates to the quality of laboratory devices and instruments used, e.g., purity of chemicals or adequacy of materials. Whenever a test is introduced, changed or used in a new context, technical validation should be triggered. There are several guidelines and quality standards for ensuring technical validity [3]. Medical validation, on the other hand, refers to the plausibility of the test results. Assuming technical validity, implausible results indicate that something went wrong with a sample retrieved from the patient, e.g., a blood sample was contaminated with another fluid, which requires re-examination.

Medical validation consists of two parts: transversal and longitudinal assessments, addressing the plausibility of results with respect to a population or to an individual [4]. Transversal assessments can be based on all patients of a hospital, for which the same test procedure was executed. This allows to set limits on the values to be expected from

¹ Corresponding Author, Murat Sariyar, Bern University of Applied Sciences, Quellgasse 21, CH2502 Biel/Bienne, Switzerland; E-mail: murat.sariyar@bfh.ch.

a test, for example in the form “the cardiac troponin values on our devices for 99% of all our patients in the last year range between 0.04 ng/L and 100 ng/L”. This type of validation is often called extreme value analysis. For longitudinal assessments, several measurements of the same parameter for the same patient are compared with each other. Plausibility in this context defines whether delta changes are within sensible limits or not. The phrase used for such assessments is “delta check”.

Our working environment was the Institute of Clinical Chemistry (ICC) of Zurich University Hospital (USZ). Several tools were in use to calculate the percentiles and produce graphical outputs, mainly Excel based spreadsheets with added functionality. The workplace of the scientific staff responsible for the validation was separated from the laboratory premises. This physical distance creates a clear separation between the day-to-day business (laboratory examinations) and the validation process, allowing high flexibility in the adaptations of workflows. In this context, we were approached to tackle the question of whether it is possible to increase the efficiency of the medical validation at ICC by business intelligence tools.

2. Methods

2.1 Review of the literature

Our literature research was based on the PubMed and Cochrane Library databases. The focus was on studies that use business intelligence and/or the statistical environment R for delta check procedures and extreme value analysis. Keywords were identified in particular through preliminary discussions with stakeholders. These were then entered into the database mask in various combinations:

- ("medical validation") AND "r statistics"
- ("medical validation") AND "business intelligence"
- ("delta check") OR "r statistics"
- ("delta check") OR "business intelligence"
- ("extreme value analysis") AND "r statistics"
- ("extreme value analysis ") AND "business intelligence"

2.2 Approaches and tools considered

For deriving requirements, we used user stories as well as uses case diagrams. The former technique stems from the agile development framework Scrum [5]. A user story informally describes features of a software system from the perspective of the user; hence, it focuses on what the user needs instead of what the system should deliver. One example in our context: User A (who) wants to calculate percentiles (what) to decide whether validation is necessary (goal). This made it possible to gain a better mutual understanding of the system [6]. Use Cases in contrast describe how the system will act. The creation of a use case was intended to concretize the functional and non-functional requirements of the system and to illustrate the interaction between user and system.

Based on the results of our requirement analysis, we developed a business intelligence application (BIA) using on Microsoft Power BI (Desktop version August 2018) and R (3.5.2). For user-system interactions and visualization, we used an

interactive HTML widget in order to improve the user experience. To implement this widget, additional R packages are required, namely *ggplot2* and *plotly*. The availability of Microsoft Power BI at the ICC and its connection to hospital wide data warehouse made it a natural choice as BI environment.

3. Results

The results of our literature research demonstrated, albeit various methodological improvements were proposed (e.g. see [7]), that there is a gap between the availability of business intelligence tools and their usage for supporting the medical validation workflow in laboratories. In addition, information on the use of expert systems within the clinical laboratory [8], on automated validation for clinical laboratory test results [9], and on the usage of Microsoft Power BI and R for business intelligence applications could be collected [10, 11].

Together with our stakeholders, we defined different workflows to be supported in shape of user stories:

- “As a research assistant, I need up-to-date clinical laboratory test data in order to perform medical validation.”
- “As a research associate, I want graphical visualizations to give me a first idea of the data shape.”
- “As a research associate, I need to calculate percentiles in order to decide whether validation is necessary.”
- “As a research assistant, I need an intuitive user interface to get around quickly.”
- “As a research assistant, I need a user manual so that I can inform myself about the individual functions of the application.”

Discussing these user stories and use case diagrams developed in the requirement analysis phase allowed us to identify following functional requirements:

- i. Interfacing to stored clinical data; in our case to clinical data in the data warehouse of the hospital,
- ii. Support for two separate validation workflows: extreme value analysis and delta check,
- iii. Possibility to specify any time span,
- iv. Filter functions to specify age ranges and sex of the population,
- v. Summary statistics and interactive visualizations (e.g., histograms)
- vi. Automated computation of several percentiles (.01, .025, .05, .95, .975, .99)

Implementing these requirements with a business intelligence software environment allowed us to digitize steps in the validation process that were previously done manually in Excel worksheets; especially, importing the data, calculating percentiles, and producing graphical outputs. In first validations of the tool, the average time for each validation was around two minutes in contrast to 30 minutes with the old solution. Due to the flexibility of the validation workflow, further adaptations can be realized rather quickly. The user interface for the extreme analysis uses filters for

selecting the population on the left panel of the page. The user can specify the laboratory test, the time period, sex and the age range. On the main panel, the results are interactively updated according to the specifications; the core result elements are an interactive histogram, the number of examinations considered, and percentiles. The user interface for the delta check was structured in the same way (see Figure 1). In addition, we included buttons for absolute (default) and relative values (the difference divided by the first value).

Figure 1: The Delta Check page of our application with filters on the left panel and results on the main panel.

Discussion

We were able to increase the efficiency of the medical validation process at the ICC by automating many time-consuming validation steps that were performed manually before. Due to the automation, reduced error rates can be expected. One important advantage of using an R-based BI tool is related to the out-of-the-box functionalities it provides, e.g., for data import, for interactive visualizations and for statistical summaries. The functional requirements list in the result section describes key requirements that typically arise in such contexts.

Development took place on a development environment. Before moving to the production environment, a few hurdles have to be considered. First, there are different Power BI versions: we used Power BI Service for development, but for security reasons (if cloud solutions are not permitted) Power BI Reporting Services should be used, which might require license update. Second, HTML widgets in one Power BI version might not work in another. Third, the graphics integrated into Power BI via R can only deal with data frames having at maximum 150,000 rows [12].

Using R comes with a lot of functionality, stemming from an open research community [13,14], that can be used for advanced statistics and machine learning (ML). Although Python gains high attention for data science applications, for visualization

and scientific-based data analysis, R is still one of the most widespread and dynamic programming environments. The use of ML in a future version could lead to an even faster validation process. The whole process of plausibility checks based on different percentiles and patient characteristics can be automated and trained by a neural network, which can be enabled to integrate many different kinds of information. The keras-package in R [15] is highly suitable for that purpose and its integration will be our next goal.

Abstract. Identifying subtypes of Alzheimer's Disease (AD) can lead towards the creation of personalized interventions and potentially improve outcomes. In this study, we use UK primary care electronic health records (EHR) from the CALIBER resource to identify and characterize clinically-meaningful clusters patients using unsupervised learning approaches of MCA and K-means. We discovered and characterized five clusters with different profiles (mental health, non-typical AD, typical AD, CVD and men with cancer). The mental health cluster had faster rate of progression than all the other clusters making it a target for future research and intervention. Our results demonstrate that unsupervised learning approaches can be utilized on EHR to identify subtypes of heterogeneous conditions.

Keywords. Phenotyping, Alzheimer's disease, Electronic health records, machine learning

1. Introduction

Alzheimer's disease (AD) is a highly heterogeneous disease. Any two individuals with the disease display a different array of symptoms or progression rate[1]. Progression rate can be increased by many factors such as higher education level and comorbidities like diabetes[2]. Gaining a complete view of a patient's profile of symptoms, comorbidities and demographic factors can enable the discovery of different progression patterns and to personalise treatments for AD patients.

Almost all subtyping studies to date in AD focuses on two data types; cognitive tests[3] and brain scans[4], showing cluster(s) of hippocampal atrophy and more diffuse atrophy, corresponding to specific memory problems and more global cognitive

¹ Corresponding Author, Nonie Alexander, Institute of Health Informatics, University College London, London, UK; E-mail: nonie.alexander.16@ucl.ac.uk

problems, leading to different patterns of progression[4]. Subtyping using electronic health records (EHR) has been carried out in many diseases[5][6] and are ideal data sets to apply these methods to due to the large sample size and the breadth of clinical information[7] they contain. Variables and outcomes are lifted directly from clinical data making them directly relevant to the patient's clinical management. This work aims to identify subtypes of AD using a range of clinical information on the patients.

2. Methods

2.1. Data and cohort

We used data from the Clinical Practice Research Datalink (CPRD)[8] which contains longitudinal primary care EHR from general practices in the United Kingdom[8]. Only patients from practices which have been marked up to standard are used and only data collected after the practice was found to be up to standard were used. Data were extracted and phenotypes defined using the CALIBER data resource[9,10]. We classified patients as cases if they had at least one AD Read code and no other future diagnosis indicating a different dementia subtype diagnosis[11]. Full case analysis was used. This study was approved to use CPRD data by the Independent Scientific Advisory Committee (ref. 18_111).

2.2. Variables and Outcomes

Three categories of variables were included in the analysis; symptoms, comorbidities and demographic and lifestyle factors. Symptoms and comorbidities were identified through a systematic literature review of studies identifying symptoms or finding associated comorbidities. There resulting symptoms found were memory problems, confusion, neuropsychiatric problems and motor problems. From them the disease that were identified were atrial fibrillation, anxiety, hyperglycaemia, rheumatoid arthritis, stroke, hearing loss, depression, kidney disease, heart failure, atherosclerosis and cancer. Age of onset, gender, drinking status and smoking status were all included as demographic variables in the analysis. The phenotypes for each symptom was ideally defined using previously defined and verified CALIBER phenotypes[9,10], if they were not available, using a definition from a previous studies.

We defined five clinical outcomes which were used to evaluate clusters: a) length of time to treatment discontinuation[12], b) rate of progression measured by the Mini Mental State Exam[13], c) healthcare utilization defined as number of appointments and missed appointments per year, d) all-cause mortality and time to assisted living, and e) time to assisted living. For the latter two, we created Kaplan-Meier survival curves.

2.3. Statistical analysis

We used Multiple Correspondence Analysis (MCA) for dimensionality reduction[14]. K-means was used to identify clusters: First, k was decided through an elbow plots for the cluster entropy, silhouette coefficient and Bayesian Information Criterion (BIC). K-means was executed 100 times to establish the optimum solution determined by the

inter cluster variation. To evaluate the clusters silhouette score were used to measure cluster structure and cluster stability was measured through Jaccard index of cluster results based on a 100 X bootstrapped sample.

3. Results

We identified 7,913 AD patients (66.2% female, mean age 82.1, 81.3-83 95% CI). Using the first five MCA principal components, we identified five clusters: mental health cluster which has the highest prevalence of anxiety and depression comorbidities, non-typical AD which had the lowest prevalence of memory symptoms and highest of other symptoms, typical AD which had high prevalence of memory symptoms and low other symptoms, cardiovascular disease (CVD) cluster with high prevalence of cardiovascular diseases such as atrial fibrillation and associated diseases such as diabetes and a cluster of men with cancer (Table 1, Figure1) all with differing clinical outcomes (Figure 2). The clusters had a silhouette score of 0.19 (showing weak cluster structure) and mean Jaccard index of 0.78 indicating overall stability.

Table 1. Each cluster name, key variables that characterise the cluster and their outcomes. Green - highest outcome. red - lowest outcome, * significant

Cluster I.D	Demographics	Top Characteristics (figure 1)	Outcomes (figure 2)
1. Mental Health Cluster	n = 1528 80.1% female onset age = 75 Diag MMSE = 21.6	Neuropsychiatric symptoms, (83.51%) Anxiety (62.11%) Depression (69.24%)	Fastest rate of progression* (2.16 mmse points per year, 2.06-2.26 95% CI)
2. Non- typical AD Cluster	n = 1640 81.3% female onset age = 86 Diag MMSE = 20.9	Memory symptoms (44.15%) Confusion(71.04%) Neuropsychiatric symptoms (98.35%)	Shortest time till treatments discontinuation (3.09 years, 3.19-2.99 95% CI) Lowest survival probability* Shortest time till assisted living *
3. Typical AD Cluster	n = 2026 90.1% female onset age = 82 Diag MMSE = 21.7	Memory symptoms (89.09%) Confusion(0.05%) Neuropsychiatric symptoms (18.85%)	Fewest appointments per year* (16.6 apps per year, 16.15-17.1, 95% CI)
4. Cardiovascular disease Cluster	n = 686 45.9% female onset age = 81 Diag MMSE = 21.4	Diabetes (84.26%) Hypertension(81.49%) Atrial fibrillation(20.41 %)	Greatest number of appointments per year* (24.8 apps , 23.7-25.9 95% CI) and missed appointments per year* (0.96 missed apps, 0.84 - 1.08 95% CI)
5. Memory problems and Cancer Cluster	n = 1710 19.0% female onset age = 79 Diag MMSE = 22.6	Memory symptoms (90.94%) Cancer(43.27%) Male (80.99%)	Slowest progression rate (1.59 mmse points a year, 1.5-1.68 95% CI)

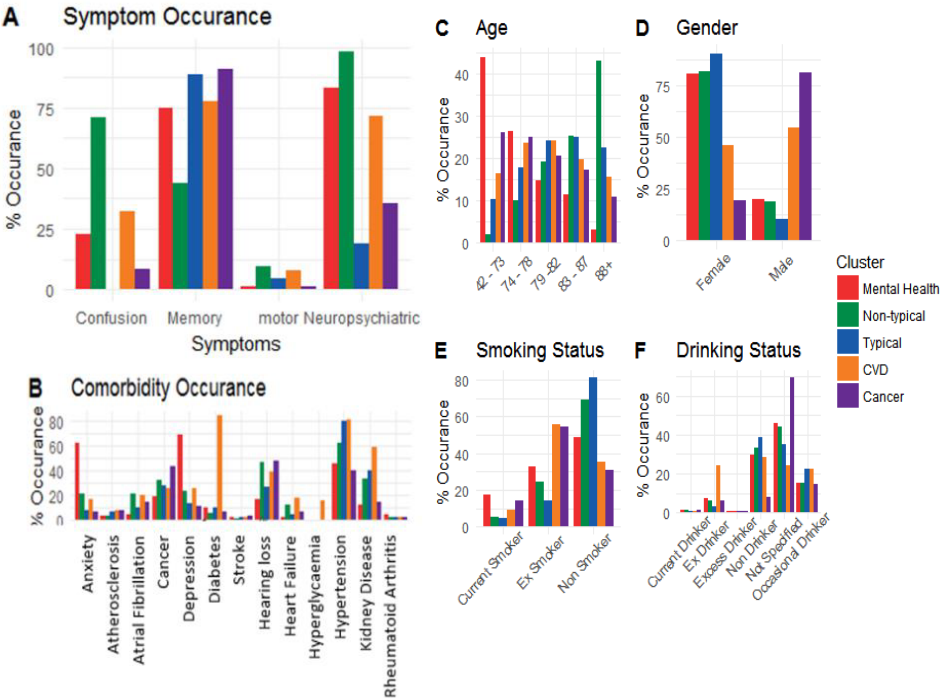

Figure 1: Distribution of the variables included in the cluster analysis for each cluster a) symptoms, b) Comorbidities, c) age, d) gender, e) clinically-recorded smoking status, f) clinically-recorded drinking status

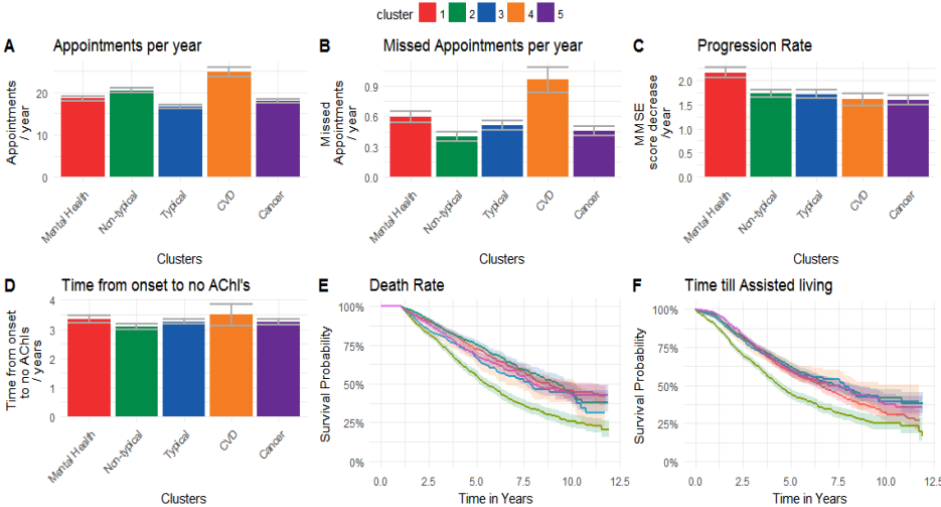

Figure 2 : Outcomes difference for variables not included in the cluster analysis per cluster: a) mean number of appointments per year with CI, b) mean missed appointments per year with 95% CI, c) mean MMSE score reduction per year with 95% CI, d) mean time to treatment discontinuation with 95% CI, e) Kaplan Meyer curve of survival probability, f) Kaplan Meyer curve on time till assisted living.

4. Discussion

Using unsupervised machine learning on a cohort of 7,913 AD patients defined through EHR, we identified five distinct clusters with different clinical profiles: a mental health cluster, a non-typical AD cluster, a typical AD cluster and clusters with mostly cardiovascular problems and a cluster with cancer. The mental health and early onset cluster had a faster rate of progression. Further research is needed to delineate the relationship between the mental health comorbidities, rate of progression and early onset. Identifying the CVD cluster can have clinical benefit as they have the highest healthcare utilization. The two clusters of typical and non-typical AD are similar to clusters found in previous research splitting patients with memory issues and patients with other cognitive issues[3]. The cluster with high prevalence of cancer, and men reported low prevalence of other symptoms aside from memory loss. There should be more investigation into whether the mechanism that leads cancer to protect against AD [2] also reduces the number of symptoms through less global atrophy. Using this data type uses a unique perspective on which to cluster patients as it offers a longitudinal and broad scope of a patient. The cluster results also have clinically relevant and impactful outcomes. There are however several weaknesses to the study such as there are some that are important but not or only partly recorded such as family history of AD recorded in EHR. Future work will look into validating these results through comparing this method with other cluster methods cluster results using imaging and cognitive test results.

Assessment of the Prognostic Accuracy of Scores in Different Ways on the Example of Assessing the Validity of the Prognostic Model ISS-RTS-TRISS

Irina V. VASILYEVA^{a,1b}, Tatyana V. ZARUBINA^b, Yuri D. UDALOV^a

^a State Research Center - Burnasyan Federal Medical Biophysical Center of Federal Medical Biological Agency, Moscow, Russia

^b The Russian State Medical University, Moscow, Russia

Abstract. The aim of the present study was a comparison of prognostic accuracy assessment results for scores in different ways on the example of validity analysis of the prognostic model ISS-RTS-TRISS for assessing the severity of the condition in children with trauma. The prospective study was conducted using clinical and physiological data collected at the admission and during the first 24 hours of hospitalization from 414 children with trauma. We had three groups of patients, common group children with traumatic brain injuries, and two groups of patients were divided into the two following ways: 141 (34%) patients with isolated traumatic brain injuries and 273 (66%) patients with combined injuries with traumatic brain injuries. The validity and prognostic accuracy of prognostic scores were assessed by determining their discrimination and calibration ability. Analysis of the discrimination ability of score was carried out by assessment the areas under the ROC curves. For analysis of the calibration ability of score was used three methods of the Hosmer-Lemeshow test (H- criterion, C-criterion in two variants). The ISS-RTS-TRISS score showed significantly outstanding predictive accuracy in studied groups (AUROC ≥ 0.9). However, estimation the calibration ability of score using the C-criterion, by dividing into groups with the same number of cases of patients (recommended for abnormal distribution) did not show an unambiguous results. It was shown that to obtain an unambiguous correct result, it was necessary to use the C-criterion method using the division of cases into groups with the same number of patients with the lethal outcome. When using this method, satisfactory results of study of calibration ability were shown for all the studied groups ($p < 0.05$).

Keywords. Prognostic score, validity of prognostic scores, prognostic accuracy of score, the Hosmer-Lemeshow test, score ISS-RTS-TRISS

1. Introduction

Modern medicine focuses on increasing the effectiveness of decisions taken during treatment, based on assessing the severity of the condition and the severity of injury in patients, predicting the likelihood of death in patients [1, 2]. One of the methods for

¹ Irina V. Vasilyeva, State Research Center - Burnasyan Federal Medical Biophysical Center of Federal Medical Biological Agency, Marshala Novikova Str. 23, Moscow, 123098, Russia, iv001yt@gmail.com

solving this problem is the using of numerous specialized prognostic scores for various nosologies and different age groups of patients [3, 6, 7, 8]. The prognostic scores, which are mathematical models that include basic demographic, clinical and laboratory data, are an example of the quantitative assessment of the severity state [8, 9, 10]. One of these scores is the ISS-RTS-TRISS (Injury Severity Score - Revised Trauma Score - Trauma Injury Severity Score) prognostic score for assessing the severity of injuries, proposed by Champion and colleagues in 1990. The score allows to assess the severity of a patient's injury and determine the likelihood of death [11]. An important point in the use of scores is the quality and validity of the predictive model, which determines the validity and suitability of the application of the technique in specific conditions, and consequently - the correspondence of the possibility of prognostic scores to the tasks assigned [5, 12, 13]

As is known, the validity and prognostic accuracy of prognostic scores can be assessed by determining its discrimination and calibration ability [3, 4, 5]. Determination discrimination ability at the moment is not difficult in the presence of matching the amount of data.

However, the determination of the calibration ability is a more complicated process and depends on the approach chosen for calculating the Hosmer–Lemeshow test [4, 5].

The aim of the present work was a compare of prognostic accuracy assessment results for scores in different ways on the example of analysis the validity of the prognostic model ISS-RTS-TRISS for assessing the severity of the condition in children with traumatic brain injuries (TBI), located in the department of anesthesiology and resuscitation in the Clinical and Research Institute of Urgent Pediatric Surgery and Trauma. To achieve this aim we set following tasks to: investigate discrimination ability of the ISS-RTS-TRISS prognostic score in groups with TBI and investigate the calibration ability of the ISS-RTS-TRISS by three ways of Hosmer–Lemeshow test.

2. Material and methods

The prospective study was performed on basis of data collected from 414 patients (mean age 9.3 ± 5 , m/f were 266/148 patients) with TBI from the age of 1 month to 18 years old who had been admitted to the Department of Anesthesiology and Resuscitation between January 2008 and January 2012 of Clinical and Research Institute of Urgent Pediatric Surgery and Trauma. 38 (9.2 %) patients died.

Criteria for including patients into the study were the following: traumatic brain injury, age till 18, availability of all necessary data for calculating results of prognostic scores, staying in the anesthesiology and resuscitation department not less than 24 hours.

We had three groups of patients, common group children with traumatic brain injuries, and two groups of patients were divided into the two following ways: 141 (34%) patients with isolated traumatic brain injuries and 273 (66%) patients with combined injuries with traumatic brain injuries (Table 1).

The assessment of severity of patient's condition and injury severity and the death risk were determined with ISS-RTS-TRISS prognostic score; these data were collected from anamnesis, initial examination, parameters of physiological and neurological

status on admission and within the first 24 hours. Score was calculated using software tools published on the Société Française de Réanimation community website [14].

Table 1. Characteristics of data for all patients and in different groups

Group patients with	N	Age (m± δ)	M/F (%/%)	Died (%)	Survived (%)
TBI	414	9.3±5	266/148 (64.3/35.7)	38 (9.2)	376 (90.8)
Isolated TBI	141	9.0±4.9	88/53 (62.4/37.6)	10 (7.1)	131 (92.8)
Combined injuries with TBI	273	9.1±4.8	171/102 (62.6/37.4)	25 (9.2)	248 (90.7)

N - sample's size of group, m - average age in the group, δ - standard deviation of mean, M – man-child, F – female-child, Died – the number of deaths in the group of patients, Survived - number of surviving patients in the group, TBI - traumatic brain injuries.

The validity and prognostic accuracy of prognostic score were assessed by determining its discrimination and calibration ability. The discrimination ability has shown a probability score to divide patients into two groups: with favorable outcomes and unfavorable (likelihood and lethal) outcomes. ROC-curve was used for evaluating the discrimination ability of the studied prognostic score [4, 5]. For analysis of the calibration ability of score was used three methods of the Hosmer-Lemeshow test. The first way was the H-criterion test with the division patients 10 groups by probability of lethal outcome. In this case, the number of patients in the intervals according to the probability of a lethal outcome wasn't the same; the number of patients who died in the intervals was also being different. The second way was the classic C-criterion of Hosmer-Lemeshow test with the division patients into probability groups of death with the same number of observed cases of patients. And the third way – the C-criterion of Hosmer-Lemeshow test with the division patients into probability groups of death with the same number of observed cases with lethal outcome of patients [5]. The data base statistical assessment and statistical description were done in Excel of Microsoft Office 2013 and IBM SPSS Statistics 20 programs.

3. Results

The investigated prognostic score ISS-RTS-TRISS showed significantly outstanding discrimination ability in studied groups (AUROC>0.9). [14]. (Figure 1, Table 2).

Table 1. Results of AUROC and cut-off of prognostic score Characteristics of data for all patients and in different groups

Group patients with	N	AUROC	p
TBI	414	0.928±0.019	<0.001
Isolated TBI	141	0.985±0.012	
Combined injuries with TBI	273	0.899±0.029	

N - number of patient in the group, AUROC –area under ROC curve, δ- standard deviation, TBI - traumatic brain injuries.

Calibration ability for score ISS-RTS-TRISS determined by H-criterion of the Hosmer-Lemeshow test showed satisfactory calibration ability for all considered groups (p<0,05) (Table 3). The classic C-criterion of Hosmer-Lemeshow test (division group into the same number of cases of patients) didn't show satisfactory calibration ability in all considered groups (p>0,05). The second C-criterion of Hosmer-Lemeshow test (division group into the same number of patients with a lethal outcome) showed satisfactory calibration ability for all groups (p<0,05). The second C-criterion of Hosmer-Lemeshow method proved to be insufficiently sensitive to assess the calibration ability of the scores with small number cases of study. Thus, the observance

of the conditions for the need for a sufficient amount of not only the general group, but also the need for a sufficient amount of the studied subgroups, taking into account favorable and unfavorable outcomes.

In general, it can be concluded satisfactory calibrating ability for all considered groups of patients with TBI.

Figure 1. ROC-curves for prognostic score ISS-RTS-TRISS in studied groups.

Table 3. Results of assessment of calibration ability for prognostic score ISS-RTS-TRISS in studied groups.

Studied groups of patients with	N	H-criterion			C-criterion (the same number of cases of patients)			C-criterion (the same number of patients with a lethal outcome)		
		χ^2	p	f	χ^2	p	f	χ^2	p	f
TBI	414	26.04	0.001	10	14.91	0.06	10	47.75	<0.001	10
Isolated TBI	141	20.26	0.009	10	3.18	0.786	8	8.71	0.033	5
Combined injuries with TBI	273	26.68	<0.001	10	15.20	0.055	10	24.09	0.002	10

N- number of patient in the study, χ^2 - χ^2 -value, p-p-value (Hosmer–Lemeshow test), f-degree of freedom, TBI- traumatic brain injuries.

This analysis of the prognostic accuracy of scales in different ways by using three methods of the Hosmer-Lemeshow test on the example of assessing the validity of the prognostic model ISS-RTS-TRISS has shown, that for sufficient validity of the results there must be, not only the total number of survived patients, but also must be a sufficient number of dead patients in the study group.

4. Discussion

Modern scientific evidence-based medicine in its practice, more and more uses complex mathematical statistical methods of analyzes.

Thus, for investigation of prognostic accuracy of prognostic scores used the determination of discrimination and calibration abilities of mathematical models. The aim of the present work was to compare of results of assessment and prognostic accuracy of scales in different ways on the example of analysis the validity of the prognostic model ISS-RTS-TRISS for assessing the severity of the in children with traumatic brain injuries.

For validated prognostic score ISS-RTS-TRISS were defined discrimination ability (AUROC >0,9) and calibration ability by Hosmer-Lemeshow test in three ways in considered groups.

Our investigation has shown satisfactory calibrating ability for all considered groups by H-criterion of Hosmer-Lemeshow test ($p < 0,05$).

The classic C-criterion of Hosmer-Lemeshow test with the division patients into probability groups of death with the same number of observed cases hasn't shown satisfactory calibration ability in all considered groups ($p > 0,05$). The C-criterion of Hosmer-Lemeshow test with the division patients into probability groups of death with the same number of observed cases with lethal outcome has shown satisfactory calibration ability for all groups ($p < 0,05$). In general we could conclude calibrating ability for all considered groups was satisfactory.

Thus, as a result of our study, it was shown that for assessment of calibration ability the Hosmer-Lemeshow test should be used, but one should take into account the number of dead and survived patients, as well as their distribution in the interval groups.

VIVID: Independent Living of Aging Adults Suffered a Stroke

Athanasios ANASTASIOU^a, Ourania MANTA^a, Dimitra ILIOPOULOU^a and
Dimitrios KOUTSOURIS^a

^aBiomedical Engineering Laboratory, National Technical University of Athens,
Athens, Greece

Abstract. Based on the recent statistics published by the Stroke Association (UK), first-time incidence of stroke occurs almost 17 million times a year worldwide (one every two seconds), making Stroke as the second cause of death in the world. By the age of 75, 1 in 5 women and 1 in 6 men will have a stroke, which is one of the largest causes of disability, as half of all stroke survivors have a disability, making those persons dependent on others (1 in 5 are cared for by family and/or friends). People living longer is a cause for celebration, but older people are more vulnerable to mental health, cognition and physical problems, especially if they have already experienced a stroke (minor or mild). Depression is a main condition after a stroke and may be experienced in the form of sadness, unexplained pains, loss of interest in socializing, weight loss etc. The abovementioned conditions reduce the person's ability to remain active and independent, affecting their well-being and quality of living. Independent living of aging adults that have suffered a stroke is the key motivation for the VIVID project.

Keywords. stroke; machine learning; personalization; virtual coach ; serious gaming; affective computing

1. Introduction

Over the past decade and based on the undeniable fact that Europe is an ageing continent, the ICT research community has responded with enthusiasm to the latest challenge: providing Europeans with healthier, safer, more independent and overall happier ageing. As Baby Boomers age, the need for adult care and assisted living continues to grow. As of February 2015, 16.4 million people in Europe receive support annually from five main long-term care service options: home health agencies, nursing homes, hospices, residential care communities, and adult day service centres. Outside these facilities, 43.5 million family and informal caregivers currently provide care for someone aged 50+.

Among the most severely disabled old persons living in Europe, about two-thirds rely solely on family members for assisted care, often resulting in great emotional stress for family caregivers. The aging population has greater chances to experience age related conditions, such as Stroke and the Post Stroke Depression. We aim to utilize intelligent multisensory and multimodal ICT devices to sense, monitor and understand human activity, in order to motivate the aging population to have a better quality of living, while improving their physical, cognitive, mental and social well-being, and furthermore to support them in their everyday living tasks. We are proposing a universal solution for any aged person in the form of a Personalized Virtual Coach (PVC) that will sense mood, activity, physical status and stress of the user (using smart environment sensors, wearable devices and voice analysis), and will interact with the user via intuitive Graphic User Interfaces and Voice Recognition. The PVC will reside in the Home Hub of the VIVID

platform, while it will be accessible via smartphone and/or tablet devices. Our solution will adopt the latest development in Human Machine Interaction and Affective Computing, to provide user-adapted and intuitive access to a multitude of enabling computer applications, designed to assist and support the welfare of the seniors. The PVC aims to reduce the decline of the physical status, the mental capacity and the cognitive abilities of seniors suffered a Stroke, including those having Post Stroke Depression symptoms, encouraging them to stay active and perform physiotherapy and speech therapy rehabilitation sessions, using body posture tracking devices and Augmented Reality headsets. Going beyond any other similar solution, the proposed PVC prototype will incorporate an ontology-based adaptive learning system to improve machine-to-machine learning, in order to enhance the identification of the user behaviour, patterns and preferences, and provide a highly customised virtual coaching experience.

2. Objectives

2.1. Develop the Smart Sensor Network (SSN) to capture the living environment and the health status of the user

Under this objective, we will investigate how we can use Augmented Reality, Serious Games, Voice Analysis and Emotional Computing to monitor how the user interacts with the living environment in their everyday living conditions. The proposed framework will be capable of using Internet of Things (IoT) enabled commercial sensors to a) "sense" the home environment of the user, and b) measure physiological parameters to assess the health status of the user. SSN will adopt UniversAAL middleware to allow the IoT enabled devices to become available, searchable, accessible, and usable by the UniversAAL to enable applications of the system.

2.2. Develop an intuitive Interaction Framework for the interaction between the user and the PVC

This objective will focus on the adoption of the intuitive Human Computer Interaction (HCI) principle in the implementation of the PVC. The interaction will be performed using four of the user's senses (sight, hearing, voice and touch). Portable devices with touch screens will be used to receive user's input, using simple and intuitive Graphic User Interfaces (GUIs). A Natural Language Processing (NLP) framework will be used to process voice commands and reply to user requests. The NLP framework will enable PVC to be built upon the use of conversational interfaces that understand and speak human language, leveraging the acceptance and maximising user friendliness.

2.3. Develop a Serious Gaming Platform supported by Augmented Reality headset

This objective will focus on the development of a Serious Gaming Platform (SGP) to be used by the elderly to perform physical and cognitive exercises. The SGP will be composed of standalone applications installed in the HH, which will update their content and exercises via internet connection. The updated content will be provided by the medical professionals and will be personalised to the individual player, supported by the IF. This module will also be used for the tele-rehabilitation (physiotherapy and speech therapy) of the users.

2.4. Improve prescription adherence along with medication compliance and persistence

Successful treatment of disease with prescription medicines requires consistent use of the medicines as prescribed. Yet research shows that medicines commonly are not used as directed. Non-adherence to medicines is a major health care cost and quality problem, with numerous studies showing high rates of non-adherence directly related to poor clinical outcomes, high health care costs, and lost productivity. Many of the human and economic costs associated with non-adherence can be avoided, making improving patient adherence one of the best opportunities to get better results and greater value from our health care system [7]. Prescription adherence and medication compliance are crucial when targeting Depression and Stroke patients. Forgetfulness and complexity of regimen are the two parameters of adherence where PVC will focus. The proposed Medication Adherence Module (MAM) will be composed of a smart pill box (an IoT connected device to manage medication disposal) and a reminder connected to the user via the IF.

2.5. Improve exercise compliance to improve physical well-being and reduce health related risks

This objective will focus on the personalised provision of the exercise plan for the users, based on the individual preferences and needs. There is clear evidence that well-designed technology interventions can effectively change health-related behaviour, improve patient knowledge and confidence for self-management of health, and lead to better health outcomes. Embedding emerging technologies into health interventions afford a real opportunity to study, understand, and positively affect human behaviour through devices which monitor human behaviour and provide an ideal platform for delivering behavioural change interventions and feedback. By improving the physical health of the seniors via the executed activities, both musculoskeletal and mental well-being will be improved, as strong muscles can reduce the risks of potential falls, and as exercise can treat mild to moderate depression as effectively as antidepressant medication. Validation of the results will be performed using the International Physical Activity Questionnaires (IPAQ).

2.6. Improve cognitive well-being to reduce memory decline, preserve language skills and maintain visual perceptual abilities

Language and vocabulary are well retained throughout the lifespan. Vocabulary continues to improve into middle age. Recall of general knowledge acquired at a young age and well-practiced skills like arithmetic also peak in middle age and are resistant to age-related decline. To be able to recall an event or new information, the brain must register the information, store it, and then retrieve it when needed. The ability to recall new information, such as reading material, becomes more challenging after the age of 40, particularly for visual material. To improve the cognitive skills of aging people, the PVC will challenge the users to play mini game, like quizzes or simple problem solving games, tailored for each individual.

2.7. Maintain mental health of the aging population to enhance the everyday feeling of well-being

Under this objective, the mental health of the seniors will be promoted, as it is an integral part of health. Good mental health is identified by WHO as a "state of well-being in which an individual realizes his or her own abilities, can cope with the normal stresses of life, can work productively and is able to make a contribution to his or her

community." With that in mind, VIVID will try and maintain the improvement of mental health via the guidance and the support of the PVC, the adoption of a healthy diet, the performance of regular moderate exercise , the adoption of patterns that offer good quality of sleep or manage stressful situations (via relaxation techniques). To achieve those targets, the PVC will encourage the user to comply with a minimum set of goals, including regular exercising, setting small incremental targets in everyday life (regarding exercise, sleeping patterns or participation in community activities) to help him/her maintain a competent mental health .

2.8. Advance the social wellness of the seniors, to let them remain active and socially connected

To maintain the social wellness of the seniors, the PVC will encourage their contribution to their environment and community. Social wellness incorporates making healthy living choices and initiating better communication with others. Social activities such as games (bingo, dominos, cards, and puzzles), parties/gatherings for family and friends or the local community, are part of the activities to improve social wellness. By helping seniors to be kept socially active, there is a decreased risk of diseases, social isolation as one of the key indicators leading to depression in seniors is avoided (the seniors maintain and continue to build new relationships). There is also proof that the immune system tends to be stronger in seniors who are active socially, while isolated seniors tend to have higher blood pressure, because the lack of social connections can lead to an elevated risk of diseases, such as cardiovascular disease .

3. Concept and methodology

The concept of the VIVID project is the development of a personalised solution, in the form of a PVC, that will use the latest advances in ICT, to motivate and support the aging

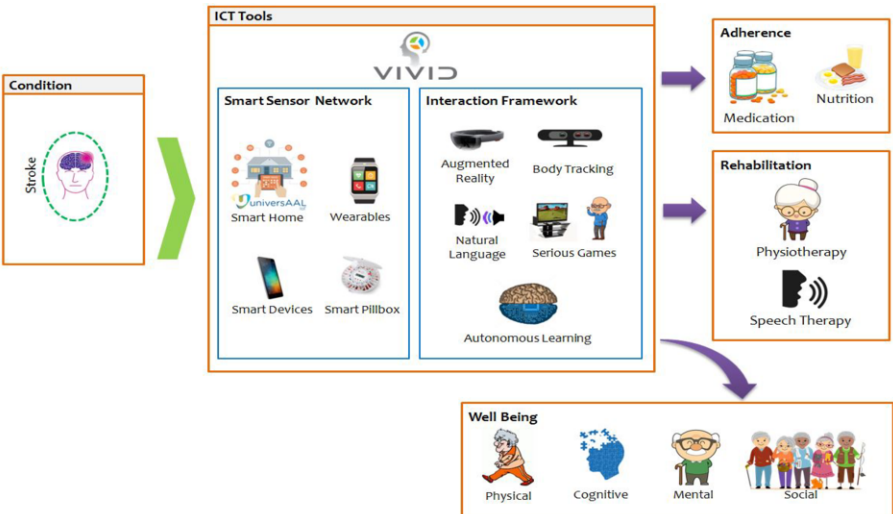

Figure 1 VIVID PVC architecture outline

adults in terms of medication and exercise adherence and their overall well-being. VIVID will develop a personalized solution in the form of a PVC, adapted to the needs of the

aging population, with focus on those with PSD and those who have suffered a SE and need rehabilitation. Our solution targets those that require rehabilitation (speech therapy or physiotherapy) after they have suffered a Stroke Episode. This will be done in such a way that will preserve the individual's dignity and will motivate him/her to re-learn basic skills that the stroke may have affected, such as speaking and walking. Figure 1 depicts the ICT tools that will be used in the proposed PVC solution offered by the VIVID project.

4. Discussions

VIVID can improve care and reduce the need to use health and care services by enabling more of our citizens to build up the knowledge, skills and capabilities they need to manage their own care and symptoms. VIVID will achieve this by engaging communities, supporting carers, and developing volunteering in and partnerships with the charitable and voluntary sector. VIVID will aid in Improvement of patients' life-space mobility (Modified Ashworth scale, Tinetti Performance Oriented Mobility Assessment, High-level Mobility Assessment Tool (HiMAT), in Permission of independent living (e.g. EQ5-D, SF-36, Interprofessional Socialization and Valuing Scale (ISVS), Care Dependency Scale, Bowel Control Scale (BLCS), Paced Auditory Serial Addition Test (PASAT), in Improvement of patients' autonomy and participation in society (Lkert scale), in Improvement of family living standards (self-reported questionnaire), in Improvement of quality of life (questionnaires of QoL – EQ 5D) and in reduction of costs for the management of the gait problems (Functional Gait Assessment). In the VIVID project the users' participation is situated in the center of the development process. Innovative user-friendly interfaces of VIVID will increase the usability and adaptability of the systems. Taking into account seniors' needs, an interactive game framework is developed and will be tested during the pilot phase. The science of behavior and personalization will help in order to build a really elderly-friendly and easily adopted VIVID system.

[†]*Equally Contributing Authors*

Abstract. Clinical Practice Guidelines (CPGs) are promoted as a powerful tool for standardization of the medical care quality and improvement of patients' outcomes. However, CPGs need to be formalized in a computer interpretable format (i.e. as Computer Interpretable Guidelines or CIGs) for their implementation within Clinical Decision Support Systems (CDSS). But, maintaining the reliability of these guidelines when deploying them in different clinical settings is still a challenge. On the one hand, the complexity of the medical language complicates the adoption of the guidelines in different clinical institutions. On the other hand, the continuous discovery of new evidence needs to be included within CPGs, updating their contents and providing tools for evidence assessment. Furthermore, although nowadays' clinical decision-making tends towards a personalized process, guidelines are designed for a general population. In this paper, we present an Authoring Tool (AT) that allows clinicians to take an active role in the process of CPG formalization. This AT enables them to introduce new clinical knowledge and create personalized CIGs for their local application, which best fits their clinical needs. The proposed system also allows the use of ontologies to facilitate the standardization and interoperability of the created guidelines. Finally, the content included in the CIGs can be evaluated using standard systems for grading clinical evidence.

Keywords. Authoring Tool, Clinical Decision Support System, Clinical Practice Guidelines, Computer Interpretable Guidelines, Ontologies.

1. Introduction

Clinical Practice Guidelines (CPGs) are a set of criteria developed in a systematic way to help professionals in the decision-making process, providing the latest evidence-based diagnostic or therapeutic options when dealing with a health problem or a specific clinical condition [1]. Over the past years, CPGs have been widely promoted to be implemented as Computer Interpretable Guidelines (CIGs) within Clinical Decision Support Systems (CDSS). Nevertheless, there is still work to be done in the maintenance and personalization of these guidelines in order to maintain their reliability when implementing them in different clinical settings. On the one hand, the complexity of medical language makes the comprehension and interoperability of the

CPGs a complicated issue, since different guidelines modeling the same clinical domain could differ in the provided knowledge. In this context, semantic web technologies such as ontologies are promoted for a standardized medical vocabulary. On the other hand, the evolving nature of medicine and the continuous discovery of new evidence needs to be included in CPGs, assessing the quality of the formalized evidence in a continuous way. To solve this issue, methodologies that assess the quality of the formalized evidence and the strength of the recommendations are promoted. Furthermore, CPGs are developed considering a population as target, not individuals, thus assuming the existence of a “standard” patient, which is not representative of all possible individual cases [2]. In this sense, personalizing guidelines using clinicians’ own experience, patient preferences or local protocols of institutions can be helpful to increase clinicians’ compliance to CDSS [3].

In this paper, an Authoring Tool (AT) that enables clinicians to formalize actively personalized CPGs in a user-friendly way by introducing new clinical knowledge and create CIGs that can be adapted to their local protocols is proposed. First, an approach for the semantic validation of the content in the guidelines leaning on an ontology is presented. Second, the methodology used for the CPG formalization process is described. Lastly, a use case in Gestational Diabetes Mellitus is shown to illustrate the proposed methodology.

2. State of the Art

The formalization process of CPG into CIGs is a complex, time-consuming task requiring technical and clinical skills to be done successfully. As a result of this, it is difficult for clinicians to create or edit the contents of existing CIGs, making necessary the involvement of a knowledge engineer for CIG management and implementation [4]. In order to solve this issue, Authoring Tools (AT) are proposed as tools for facilitating and actively taking part in the creation of CIGs by clinical domain experts. To avoid the technical encoding, clinicians are provided with user-friendly and interactive interfaces that ease the formalization process [5].

For example, Dunsmuir et al. [6] developed an AT in order to enable anaesthesiologists to include their clinical knowledge in a rule-based CDSS. Their AT allows users to introduce and edit clinical rules, but requires the user to have knowledge about XML files in order to edit the terminology and parameters used by the AT. Furthermore, the format used to encode clinical rules is designed for its use in anaesthesiology, which makes it too specific for its adoption in other clinical domains.

Another example would be in the case of Ali et al. [7], who propose a framework that makes use of HL7 standard and ontologies in order to generate shareable CIGs. Rules are created and edited using an ontology-linked AT, and Arden Syntax is used to represent them. While the constructed rules follow a standard to encode the clinical knowledge, no standard systems for grading clinical evidence are used.

In this work, following the approach by Muro et al. [8], an AT for developing domain independent CIGs is presented. This proposal uses the Decisional Event (DE) structure to store the clinical information regarding the decision-making process. Using this structure it is possible to compute the quality of evidence and strength of recommendation for each of the rules, as described in [9]. As our platform is based on this DE concept, the strength of the recommendations in the CIG can be assessed.

3. Methodology

The proposed AT, within the architecture shown in Figure 1, is composed by:

- (i) a module for interacting with external knowledge models, such as ontologies, to provide the needed clinical domain knowledge during the formalization process,
- (ii) a user-friendly Graphical User Interface (GUI) as the frontend of the system for introducing rules that will compose the final CIG, and
- (iii) a backend, which is responsible for creating the final CIG.

To ease the technical comprehension of this chapter, it is supported by a use case in the management of gestational diabetes.

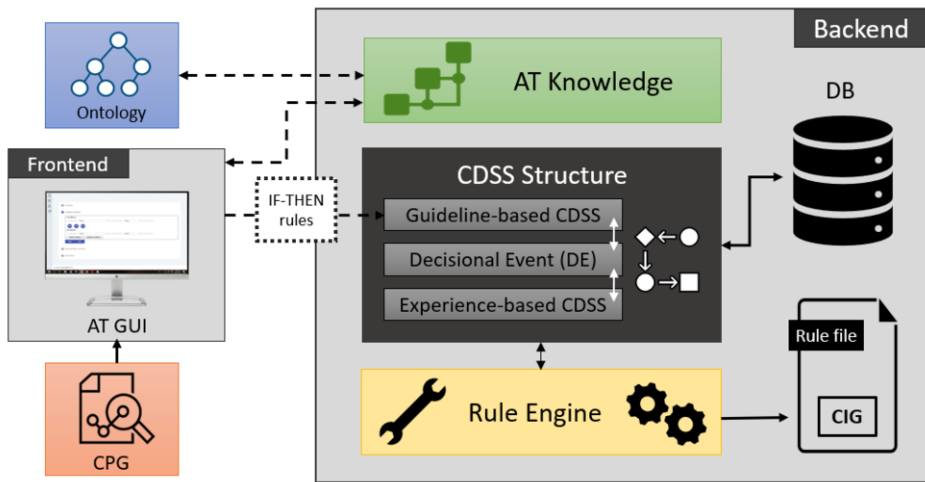

Figure 1. General view of the framework.

3.1. Interaction of the AT with ontologies

Ontologies formalize the clinical knowledge in a standard, flexible and interoperable way. In this approach, ontologies are externally queried to provide the needed clinical domain knowledge during the formalization process. After a research on different APIs for the integration of ontologies with the CDSS, Apache Jena¹ was selected, as it allows our development to integrate ontologies using RDF or OWL models in an easy way.

For the interaction of the AT with the ontology, different web services are used to:

- (i) get the list of variables (classes) from the ontology for defining the variable names within a rule,
- (ii) obtain the possible values of the selected variables, and
- (iii) receive the list of recommendations for completing the consequent part of the rule. This interaction can be seen in Figure 2, where the possible values that a

¹ <https://jena.apache.org/documentation/ontology>

variable (“*CurrentPhysicalActivityLevel*”) can take (left) and a recommendation as the consequent part of a rule (right) are shown.

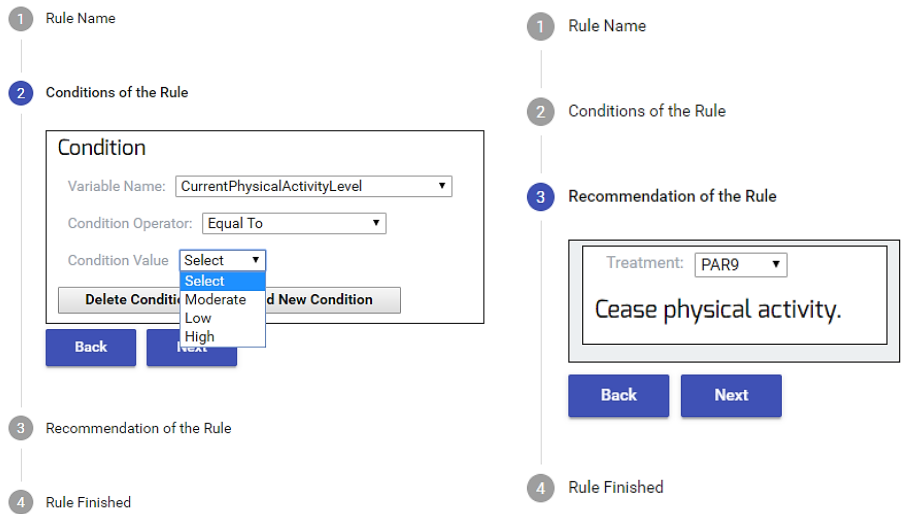

Figure 2. Introduction of conditions (left) and recommendations (right) of rules in the AT.

3.2. CPG formalization

The process of CPG formalization is the result of a continues interaction between the frontend and the backend of the system. The proposed GUI allows the user to formalize rules following four simple steps (see example in Figure 2). First, the name of the rule is defined, which defines the clinical content in a textual way. Afterwards, the conditions of the rule are introduced, defining the statements to be accomplished by the studied patient. Next, the recommendation for the formalized rule is specified as the consequent part to be provided. Finally, the rule is sent to the backend where it is stored and added into the knowledge base of the CDSS to be triggered for new cases study.

The backend supporting this AT is composed by (i) a knowledge layer linked with external knowledge models, such as ontologies, to provide the needed clinical domain knowledge during the formalization process, (ii) a structure layer that gathers all this clinical knowledge and formalizes it in a technology-independent way relaying in the DE concept explained in [9], (iii) a rule engine that integrates a rule file generator for automatic triggering of the formalized knowledge, and (iv) a database (DB) that stores the formalized rules.

With the interaction between the frontend and the backend of the system, the rules in the formalized CIG can be retrieved for their edition and update. Moreover, the used DE structure allows to write down CIGs in any document-based format (e.g. .drl, .xml, .json), since the knowledge is built in a java-based structure [8]. Finally, using the information stored in the DE concept, it is possible to apply standard metrics for

grading clinical evidence such as GRADE² to assess the quality of the evidence included in the guidelines.

4. Conclusions and Future Work

In this paper an Authoring Tool (AT) for the formalization of CPGs into CIGs is presented. This AT allows clinicians to take an active role in this process, as it enables them to formalize CPGs and personalize them according to their own experience. Also, the system facilitates the maintenance and shareability of this knowledge, as the followed DE structure can be exported into other clinical standards. With the use of this DE concept, the clinical evidence of the recommendations obtained from the system can be evaluated. In addition, the proposed system is domain-independent, allowing to formalize CPGs from different domains using the same AT. The generated CIG can then be integrated in a CDSS to provide patient-specific recommendations. Furthermore, new clinical knowledge can be added to the CIG using the AT GUI in order to update its contents with the latest evidence-based clinical practice.

Overall, the presented tool eases the formalization of CPGs into CIGs for clinicians or knowledge engineers, while also allowing to edit and update the introduced knowledge. Furthermore, tools for assessing the reported clinical evidence in the CIGs are provided, avoiding the inclusion of erroneous or low evidence-based knowledge.

Future work will include a visualization of the constructed rules to aid the clinicians' understanding how the introduced knowledge is being formalized. Finally, an ontology editor will be implemented for visualizing its classes and easing the manipulation of the ontology's contents.

Abstract. This article proposes the analysis of the admissions to hospital-at-home service within the framework of process mining. In addition to conventional modeling in standard languages, relying on interviews and continuous improvement, we propose the adoption of an automatic process discovery technique based on data collected by the hospital information system. We focus on the patient admission process, in which staff discriminate cases of interest for the service. Our methodological framework starts with the extraction of process information from the existing dataset. Once obtained meaningful data for an event log analysis, we propose the adoption of a process discovery algorithm by using a specific tool for process mining. In the context of Business Process Management, we suggest a practical application to be explored in order to improve standard modeling, opening the way to perform business process simulation with scenario analysis.

Keywords. Business Process Management, Process Mining, E-health, Hospital-at-Home

1. Introduction

In Medicine, one of the important aspects to investigate is the organization of health processes, by considering an holistic and systemic approach. In this direction, computer science gained a relevant role for technical hardware and information systems improvements [8]. This is the case of Business Process Management (BPM) [7], a discipline combining data science and management studies to perform business process improvement, modeling and simulation [19] for decision-making [2], also in healthcare [12,15]. Modeling usually adopt standard languages, e.g. BPMN², as well as relevant data collected from Process-Aware Information Systems [8], properly stored with the recent XES format [3]. Such workflow analysis facilitates the detection of inefficiencies, bottlenecks, constraints, and risks [20,5,18].

In this paper, we explore the adoption of a process discovery technique from Process Mining [9], a recent and promising field of study, in order to automatically extract

¹Corresponding Author, email: emilio.sulis@unito.it

²See OMG, Business Process Model Notation: <https://www.omg.org/spec/BPMN/2.0/About-BPMN/>

relevant information from event log data concerning the patients workflow [1]. We focus on a specific healthcare service, the Hospital-at-Home service (HaH) in Torino, one of the largest city of Italy, to investigate the admission process³.

The availability of real data about the service is at the core of healthcare business process mining perspective [13,16]. Nevertheless, the adoption of Process Aware Information System (PAIS) in most hospitals is not yet achieved, and healthcare managers more often deal with conventional aggregated information. A large part of hospital information systems actually is not well equipped for process analysis, whereas data can be difficult to extract, including several well-know problem concerning data quality [14].

This work focuses on two research problems: i. Can we derive digital information even in the absence of an information system that accurately collects data? ii. On this basis, can we automatically derive an healthcare process, e.g. the HaH admissions? We improve similar works which addressed the specific topic of modeling home-care services [17], by applying process discovery technique to data of the service.

In the following of the paper, we introduce our use case, dataset and the methodological framework in Section 2, while Section 3 includes the output of process mining. We draw some conclusions in Section 4.

2. Use case, data and methodology

The scientific literature as well as the practical experiences have already recognized the usefulness of domiciliary cares, pushing hospitals to operate with integrated territorial services [21].

2.1. Description of the use case

In the context of HaH carried out since 1985 by the main hospital in Torino, one of the biggest city in northern Italy, we focus on the experimental project of geriatric home hospitalization, in Piedmont region. This service started in the Molinette Hospital within the “City of Health and Science” of Torino, which actually is one of the largest public health hub in Europe⁴. This innovative service ensures cares mostly for elderly and fragile people in acute disease. In addition to institutionalized services for patients, HaH provides a relevant support to caregivers and their relatives. This avoids the improper accesses to Emergency services, contributing in the reduction of the consistency of waiting lists. The main interest of hospital managers to investigate HaH by adopting a process-oriented perspective relies in the evaluation of benefits to further extend this kind of service.

2.2. Business process modeling and data analysis

In Figure 1 we provide a brief overview of HaH service, focusing on admission process, whose diagram is on the left part. Eligible patients for the service are interviewed by a Case Manager (CM), to investigate and evaluate the existing conditions to apply for HaH.

³This research is part of the project “CANP - CAa Nel Parco” of Regione Piemonte funded by POR FESR PIEMONTE 2014-2020. Web site of the project: <http://casanelparco-project.it>.

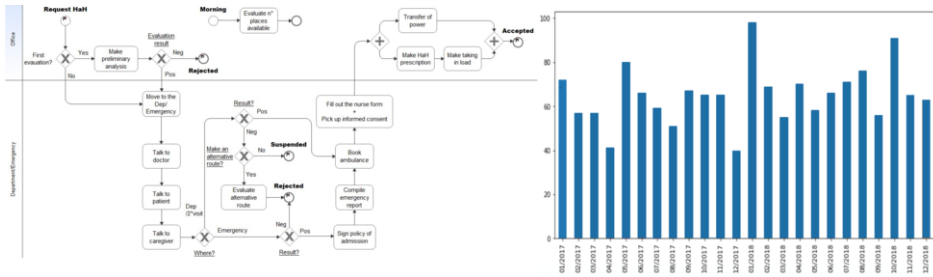

Figure 1. On the left: business process analysis in BPMN. On the right: Arrivals of patients at the HaH service in 2017 and 2018 in the different months.

The diagram describes the output of a conventional approach with BPMN. Due to lack of relevance in this paper, we avoid to detail all the tasks and passages, better presented in [4]. In addition, we perform traditional data analysis to contextualize the process of interest. The histogram in the right side of Figure 1 summarizes the arrivals of patients in last two years by months, with peaks corresponding to the periods of flu (January and Autumn), and less requests near Italian festivity days (i.e. April for Easter festivities).

2.3. Log of the process

To promote a business process analysis, we need more information about the patients' flow. An initial step in the construction of the admission process includes the exploitation of data registered in the hospital information system. As in the log example presented in the following paragraph, we extracted information including: patient's number (ID), corresponding case (SDO), provenience (PROV), first call to the CM for the evaluation (CALL), admission date (HaH1), type (OUT) and date of dismissal (END).

ID, SDO, PROV, CALL, HaH1, OUT, END

045, 2017500110, SPEC, 02/02/17, 06/02/17, ORD, 14/02/17

048, 002017500552, PS, 21/06/17, 27/06/17, TRASF, 09/07/17

045, 2018500025, MDB, 04/01/18, 04/01/18, DEC, 25/02/18

2.4. Process Mining in Health

To perform the discovery of the process from the log we adopted PALIA Process Discovery algorithm [10]. In particular, we apply PALIA algorithm for discovering the process of HaH events described in previous section. PALIA Algorithm has been successfully used in several medical problems like surgery [10], Emergency Rooms [11], or Diabetes [6], among other health solutions. Process Mining can support healthcare professionals in the real understanding of the process, not only by discovering the process but also performing assessments for enabling the application of Value based healthcare [11].

3. Results

The result of our process mining technique is the model presented in Figure 2, whereas the admission process has been automatically extracted from raw data.

Figure 2. Output of the admission process

The process starts with the patient admission (HaH1) preceded by a call by the Case Manager (CALL0), and followed by three types of output: the ordinary management of HaH activities (ORD) until the dismissal (END), the transfer of the patient - e.g. surgery or the recovery to an Hospital department (TRAS1); or the patient’s death (DEC).

A second model is presented in Figure 3, describing also the amount of occurrences. Here, the color reflect the frequency of each event: as occurrences increase, arrows and circle tend to red color. As clearly stated by the figure, the most frequent output is patients hospitalization (only once time) and then the ordinary discharged.

Figure 3. Process discovery from HaH admission dataset.

By investigating our dataset, we immediately observe how the service performs well, in general, as most patients are discharged in an ordinary way. In fact, a further investigation identifies how most patients, once discharged, do not return to the hospital. In addition, it can be observed that the number of re-hospitalization is not very relevant.

4. Conclusions

We applied process mining to data about the admission of patients in healthcare service. One point of interest is to demonstrate the ability to perform a healthcare process analysis, by automatically deriving information about processes from not well structured data (i.e., data not registered in standard event log XES format), as actually most hospital information systems are still not process-aware. We believe that the understanding of the advantages of using process mining techniques will push towards a wider adoption of PAIS in the near future, as it is actually happening in Industry. As a matter of fact, the methodological framework here presented allows to compare traditional process analysis with the emerging techniques of process discovery, opening the way to perform conformance checking and enhancement.

Abstract. In this paper we present work on creating and evaluating a Text-to-Speech system for the Albanian language to be used in the BabelDr medical speech translation system. Its quality was assessed by twelve native speakers who provided feedback on 60 prompts generated by the synthesizer and on 60 real human recordings across three dimensions, namely comprehensibility, naturalness and likeability. The results suggest that the newly created voice can be incorporated in the content creation pipeline of the BabelDr platform.

Keywords. Text-to-Speech, Albanian, Tacotron 2, BabelDr

1. Introduction

The ever increasing movement of people worldwide poses new challenges for healthcare institutions across Europe in particular problems related to different language and cultural barriers experienced by the healthcare practitioners and their foreign patients [1], [2]. Most of the time experienced interpreters, relatives or friends try to bridge this communication gap. However, this solution is often less than satisfactory as trained medical interpreters are both scarce and expensive, family members might not communicate the exact meaning of the physician's question or the patient's response, while there are also privacy concerns. It is generally agreed that translation quality is of prime importance in this setting [3], while tools like Google Translate pose certain problems on reliability and data privacy.

Since 2017 the Faculty of Translation and Interpreting of the University of Geneva and the Geneva University Hospitals (HUG) joined forces for building a medical speech translator, under the BabelDr project² funded by the Fondation Privée des HUG. The system is a web based tool that has been specifically designed to assist in triaging of non-French-speaking patients visiting HUG's A&E department, and allows a medical

⁶ <https://github.com/NVIDIA/waveglow>

professional to perform a preliminary medical examination dialogue to determine the nature of the patient's problem and the appropriate action to take. The system incorporates state-of-the-art technologies like speech recognition (ASR) and text-to-speech (TTS) and supports translation for different language pairs [4]. It is also aligned with mainstream research findings [5] on the basis that it incorporates preset health related questions and declarative sentences (11.134 in total) that can be selected using around 1M variations of similar speech phrases.

In the context of this work we created and evaluated a synthetic female voice for the Albanian language based on Tacotron 2, a neural network architecture for speech synthesis directly from text [6] that can be used for announcing the physician's questions to an Albanian speaking patient. In this paper we present the data gathering process and the steps taken in order to train the TTS. Based on an evaluation with twelve native speakers we assessed the comprehensibility, naturalness and likeability of the newly created voice. According to our findings we can reasonably argue that the synthesized voice can be incorporated in the content creation pipeline of the BabelDr platform.

Section 2 presents the methods used for gathering audio data, training the voice and evaluating its quality. Section 3 reports on the results of the training process and the feedback from the native speakers. Section 4 discusses the findings and different implications in more depth. The final section concludes.

2. Method

2.1. TTS training

As in every training task that involves a neural network architecture the amount of data is a crucial factor. Using an in-house web-based recording tool and an intermediate fidelity microphone we asked a female subject to perform 10452 recordings from home using a sampling rate of 48 kHz. The text included questions from 13 diagnostic domains with phrases like: "Can you show me with the finger where the pain is?", "Are you allergic to antibiotics?", "How many cigarettes do you smoke per day?", etc. The created corpus contained 2014 unique words, while the average length of the sentences was 14 words (sd=6). The corpus was split into a training set consisting of 9500 sentences and an evaluation set with 952 sentences. Approximately 9.5 hours of speech were recorded.

2.2. Human evaluation

Contrary to other evaluation tasks, where software systems can be assessed in terms of various objective measurements, evaluating a synthesized voice is highly subjective. For this reason we recruited twelve native Albanian speakers and asked them to provide their feedback across three dimensions typically encountered in TTS evaluations [7]. Specifically, they had to listen to a series of audio prompts and express their opinion in a five-point Likert scale (subjective mean opinion score - MOS) concerning how comprehensible the prompt is, how natural the voice sounds and how much they like the voice. The whole evaluation was set-up as a Google form³ so that the participants could provide their feedback easily, while the investigators of the study could acquire their responses immediately. The evaluation protocol was based on two hypotheses:

- The TTS can be used in our content creation pipeline.

- The TTS works equally well for short and long sentences.

For testing the two hypotheses we generated 60 audio prompts with the TTS and selected randomly 60 volume normalized recordings from the initial training corpus. For each of these two subsets we chose sentences of different word length according to this formula: 20 sentences with 1 to 3 words, 20 sentences with 4 to 9 words and 20 sentences with more than 9 words. The human recordings and the TTS prompts were merged and shuffled into a single set, so that participants were not aware of the source of each one.

3. Results

3.1. TTS training

The TTS engine was trained based on a Tacotron 2 implementation⁴ using the following hyper-parameters: learning rate=0.0001, batch size=32 and epochs=1000. The model had to learn ~28M parameters and the process took place on a Linux server equipped with an NVIDIA GeForce GTX Titan X, 12GB GPU card. Figure 1 shows the average total loss (average of the linear loss, mel loss and stop loss) in respect to the training epochs, which reaches to 0.01 at the last one.

Figure 1. Average total loss per number of epochs

3.2. Human evaluation

Table 1. Mean opinion score (MOS) for the three evaluation criteria: Comprehensibility (C), Naturalness (N) & Likeability (L) and for the two types of prompts

	I understand the question (C)	The voice sounds natural (N)	I like the voice (L)
TTS MOS	3.9 (sd=0.5)	3.0 (sd=1.0)	3.1 (sd=1.1)
Recordings MOS	4.5 (sd=0.4)	4.2 (sd=0.9)	4.1 (sd=0.9)

Table 1 summarizes the mean opinion score of all participants, for the three evaluation criteria and the two types of prompts. As expected human recordings outperform the TTS in all dimensions. Although the TTS might sound less natural and be less likeable it is still quite comprehensible 3.9/5 vs. 4.5/5 (statistically significant difference at $p<0.002$). We also examine the variation in comprehensibility, naturalness and likeability of the TTS based on the sentence length. As it can be observed in Table 2, our initial hypothesis

is correct and the TTS works equally well for short and long sentences (no statistically significant differences).

Table 2. Mean opinion score (MOS) of Comprehensibility (C), Naturalness (N) & Likeability (L) of the TTS prompts based on the sentence word length

	MOS (C)	MOS (N)	MOS (L)
Sentences with 1-3 words	3.8 (sd=0.6)	3.0 (sd=1.0)	3.1 (sd=1.1)
Sentences with 4-9 words	4.0 (sd=0.4)	3.1 (sd=1.0)	3.1 (sd=1.1)
Sentences with more than 9 words	3.9 (sd=0.6)	3.0 (sd=1.0)	3.0 (sd=1.1)

3.3. Qualitative analysis

In order to qualitatively analyze the source of errors in the synthesized prompts we asked two experts to identify possible problems. Specifically, each expert had to assess each prompt based on possible intonation problems (e.g. not being able to distinguish if it is a question or a request) and whether the prompt included muffled or unnatural sounds. These criteria were selected on the basis of informal feedback by the participants of the evaluation task. We calculated the Cohen’s Kappa score for each one of the two pairs that expresses agreement corrected for chance, shown in Table 3. A kappa ranges between -1 and 1 and a value of 0.19 is defined as slight agreement whereas a value of -0.27 as a poor one [8]. The last row shows the absolute number of sentences where the two experts agreed.

Table 3. Cohen’s Kappa for the two kinds of possible problems (95% confidence intervals in parenthesis) and absolute sentence agreement

	Intonation problems	Muffled or unnatural sounds
Cohen’s Kappa	0.19 (0.1, 0.34)	-0.27 (-0.51, -0.04)
Agreement	30 out of 60	25 out of 60

We also calculated the correlation between the MOS of comprehensibility (continuous variable) and the responses from each expert and for each one of the two criteria (categorical variables “0” or “1”). The appropriate method in this case is the point biserial correlation, which did not show any significant differences. Both correlation and agreement suggest that using intonation and checking for unnatural sounds is not an appropriate method for assessing prompt comprehensibility, which should be determined on a case-by-case basis with other criteria.

4. Discussion

In the era of neural networks creating a new voice from scratch demands few human months of work something that a decade ago would require extensive expertise and commitment for much longer time. After the positive experience with the Albanian TTS we are capable of creating new voices according to the needs of the project. Resorting to a commercial TTS is not always an option due to the lack of support for certain languages; a typical example is Tigrinya, frequently encountered at HUG, for which no synthetic voice yet exists. Even for those languages where a commercial option is available it normally targets the most common dialect. Arabic is another typical example.

On the other hand one might argue in favor of recording every new sentence from scratch. This option is well aligned with the BabelDr project which is strongly biased

towards quality assurance. Every translation is checked by experts to avoid possible errors and ambiguities. The sole difference, however, is that multiple people can perform the translation task but a single person can do the audio recordings. If this person is temporary not available the whole deployment pipeline is stalled. Even as a backup strategy having your own TTS presents many competitive advantages. Nonetheless there is always a human in the loop in our content creation pipeline that checks both translations and TTS prompts and decides if they are acceptable or not.

A factor that was not properly addressed in this study concerns on how we measure comprehensibility. In essence by asking participants to quantify their understanding you risk obtaining a negative answer for a perfectly oralized prompt simply because the question was ambiguous or unclear in the first place (e.g. a medical term was used). In a future study two levels of comprehensibility should be scrutinized by carefully creating and testing a corpus that alleviates this deficiency. Conversely, even a perfect score in comprehensibility does not decisively mean that the prompt sounds perfect. The participants expressed concerns that sometimes they listened to sentences that did not sound completely right but were still comprehensible.

5. Conclusion

Language barriers often cause inconvenience but when medical issues are involved they cease to be mere inconvenience and can become life-threatening. In this work we include a new building block in our platform for creating synthesized voices. After evaluating its feasibility for the Albanian language with twelve native speakers we can include it in the BabelDr content creation pipeline. We have also found that there are no differences in quality between short and long sentences.

In the future we plan to combine Tacotron 2 with a neural Vocoder like WaveNet⁵ and WaveGlow⁶ that promise to ameliorate the output quality. We also intend to gather more data for Albanian, as 9.5 hours of training material puts us in the low end of complexity (e.g. in [6] around 25 hours of speech were used). We will also create a new voice for the Tigrinya language.

Are Clinical Decision Support Systems Compatible with Patient-Centred Care?

Vije Kumar RAJPUT^a, Jack DOWIE^{b,c1}, Mette Kjer KALTOFT^c

^a*Stonydelph Health Centre, Tamworth, UK*

^b*London School of Hygiene and Tropical Medicine*

^c*University of Southern Denmark*

Abstract. Few, if any, of the Clinical Decision Support Systems developed and reported within the informatics literature incorporate patient preferences in the formal and quantitatively analytic way adopted for evidence. Preferences are assumed to be ‘taken into account’ by the clinician in the associated clinical encounter. Many CDSS produce management recommendations on the basis of embedded algorithms or expert rules. These are often focused on a single criterion, and the preference trade-offs involved have no empirical basis outside an expert panel. After illustrating these points with the Osteoporosis Adviser CDSS from Iceland, we review an ambitious attempt to address both the monocriterial bias and lack of empirical preference-sensitivity, in the context of Early Rheumatoid Arthritis. It brings together the preference data from a Discrete Choice Experiment and the best available evidence data, to arrive at the percentage of patients who would prefer particular treatments from those in the listed options. It is suggested that these percentages could assist a GRADE panel determine whether to produce a strong or weak recommendation. However, any such group average preference-based recommendations are arguably in breach of both the reasonable patient legal standard for informed consent and simple ethical principles. The answer is not to localise, but personalise, decisions through the use of preference-sensitive multi-criteria decision support tools engaged with at the point of care.

Keywords: Clinical Decision Support System, guidelines, GRADE, multi-criteria decision support, osteoporosis, rheumatoid arthritis

1. Introduction

Clinical Decision Support Systems (CDSS) can approach the eponymous task in a variety of ways, but this variation is within the taken-for-granted assumption, understandable in the context of ‘informatics’, that the basic support for the clinical decision at the point of care is in the form of information. However, it is clear that this excludes information on patient preferences. The aim here is to question this practice and argue for a rethinking of CDSS that would bring them into line with recent moves toward patient- and person-centred care. To avoid any suggestion of misrepresentation we start with a mainstream definition [1], with which all the CDSS presented, as such at MIE and Medinfo conferences in the last five years are in line.

¹ Corresponding author: Jack Dowie, LSHTM, 15-17 Tavistock Place, London, UK WC1H 9SH; email: jack.dowie@lshtm.ac.uk

Clinical decision support systems (CDSS) - defined as any system designed to improve clinical decision-making related to diagnostic or therapeutic processes of care... use specific parameters (such as diagnoses, laboratory results, medication choices, or complex combinations of clinical data) to provide information or recommendations directly relevant to a specific patient encounter at the point of care... CDSS address activities ranging from the selection of medications (e.g., the optimal antibiotic choice given specific microbiologic data) or diagnostic tests (e.g., the best blood test to evaluate a patient with possible pulmonary embolism) to detailed support for optimal drug dosing and support for resolving diagnostic dilemmas... Typical CDSS suggest default values for drug doses, routes of administration, and frequency, and offer more sophisticated drug safety features such as checking for drug allergies or drug-drug interactions[1].

The AHRQ summary goes on to suggest that the advent of advanced analytic methodologies for large, complex data sets and the development of machine learning techniques is likely to lead to the development of increasingly powerful and sophisticated CDSS. 'These artificial intelligence approaches have tremendous potential for transforming diagnosis and therapy.... However... acceptance of artificial intelligence-based CDSS will require transparency around the methods used to develop recommendations...'. Otherwise the spectre of 'digital paternalism is raised.

Crucially, there is no reference to preferences, which are necessary in any 'selection', 'optimization', or 'recommendation' task. Confirming the basic point of this paper, *Patient-centered* clinical decision support systems (PCCDS) are regarded by AHRQ as a separate category of CDSS: 'PCCDS refers to decision support systems that support individual patients, caregivers, and health care teams in health-related decisions and actions by leveraging patient-specific information (e.g., patient-generated health data) and patient-centered outcomes research findings...'. However, even here, the patient is only as a source of biomedically relevant information, not of preferences.

We employ a simple three-level taxonomy. A *basic CDSS* confines itself to producing biomedical information to assist the clinician to arrive at the best possible diagnostic judgment and therapeutic decision recommendation for this patient, *containing no further guidance or assistance*. This information can range from a single piece of data on a single parameter, such as this patient's bone mineral density (BMD) as measured by a DXA scan, to the output of a multi-attribute model yielding a probability for this patient experiencing a hip fracture in the next ten years (e.g. Frax). A *diagnostic CDSS* goes further, applying embedded *guidelines and/or algorithms to this data* to help the clinician arrive at the best possible diagnostic judgment for this patient - such as whether they meet the criteria for a diagnosis of osteoporosis or osteopenia according to the BMD result. Finally, a *therapeutic CDSS* applies embedded *guidelines and/or algorithms to the basic data and/or diagnostic suggestion/s* to help the clinician arrive at the best possible therapeutic decision recommendation for this patient - such as applying the National Osteoporosis Guideline Group's Frax thresholds for reassuring, treating without testing, or treating and testing. ('Diagnostic judgment' covers the entire range from a single diagnosis to a probabilistic differential diagnosis. 'Therapeutic decision recommendation' refers to any test and/or treatment option).

2. Osteoporosis Advisor: A conventional CDSS

We have already used bone health and fragility fractures as examples and now explore Osteoporosis Advisor (OPAD), an Icelandic commercial product distributed through professional providers and exclusively for use in association with a clinical encounter [2,3]. To document what is, and what is not, in OPAD, we quote at length:

... the Osteoporosis Advisor or OPAD ([http:// www.expeda.is](http://www.expeda.is)), a computerized clinical decision support system to assess and treat osteoporosis in a primary care setting... OPAD provides a patient's 10-year fracture probability (with or without BMD values) using a speedometer-like output that users can easily understand. The OPAD also notes whether a patient would benefit from BMD measurement by DXA. OPAD provides patients with lifestyle and treatment recommendations to reduce their fracture risk, incorporating country-specific guidelines for therapy... OPAD not only gives the fracture risk, but also recommend clinical decisions based on guidelines... Further patient factors may be incorporated into the risk assessment model of OPAD, such as loss of height, history of falls and it is even possible to add individual genotypes to improve the fracture risk estimation [2] (pp. 2, 6, 7).

Notably these 'further patient factors' do not include their preferences. The word 'preference' does not appear in this paper or the earlier companion one. As in most therapeutic CDSS, the patient is a biological object to be subjected to a biomedical assessment, followed by the application of guidelines incorporating either population-based thresholds (NOGG) or, as in OPAD, local expert-based rules (unpublished).

It seems fair to characterise OPAD as a good example of the 'digital' (i.e. data-driven) paternalism' that underlies many therapeutic CDSS.

The busy clinician may have difficulties in interpreting the risk value figure for each patient in hectic daily clinical practice. With this in mind we have extended the information provided by OPAD, by giving a specific diagnosis, that is, osteoporosis or osteopenia, and specific recommendations on prevention, time of next DXA, and treatment options according to international guidelines and experts knowledge... The clinically relevant parameters and the computed risk for fracture are used as input into an expert system which gives specific recommendations for each case with respect to lifestyle changes and treatment options... the system predominantly relies on knowledge capture process of the expert panels, as guidelines never cover all cases. In the end a total of fifteen different treatment recommendations were initially identified as possible recommended treatment options for osteoporosis. The recommended treatments ranged from no treatment to specific recommendations for which drug class was the most appropriate, either as a preventive measure or as a treatment for manifest osteoporosis... [3] (pp. 5,2,3).

There is nothing in any of these statements that would preclude the explicit mention of patients', or patient's, preferences, but there is none. The taken-for-granted assumption is that the latter can - and by implication should be - left to be 'taken into account' by the *clinician*, subsequent to the *clinician's* engagement with the CDSS. Why do CDSS feel justified in producing therapeutic decision recommendations without any reference to information on patient values and preferences?

One answer is that, in line with the embedded algorithm or guideline, many CDSS assume the decision is monocriterial not multicriterial. OPAD assumes that the only criterion that matters is fragility fracture prevention, ignoring all other outcomes (and process considerations) involved in the options. The side effects and treatment burden of the various options are two criteria given significant weight by many patients. In the

piloting of a Danish decision support tool the weights given to avoiding fragility fracture in the next ten years was 43%, to avoiding (option?) side effects 37%, and to avoiding bother/burden 20% [4]. Other populations, settings, and methodologies are likely to produce different results, but highly unlikely to produce anywhere near 100% weight to fragility fracture prevention. It is not a convincing response that these criteria are also to be dealt with outside the CDSS. If a CDSS does not attempt to address a decision as the multi-criterial one it is - probably using some version of Multi-Criteria Decision Analysis [5] - it would be more appropriately called a Clinician Information Support System.

The second answer is that, even absent 'digital paternalism', it is extremely difficult to deal with preferences 'scientifically', since this requires (a) their elicitation and (b) the integration of the results into the decision or guideline. It is not surprising, then, that only in 2019 have we seen a paper attempting it [6].

3. A multi-criterial, group preference-sensitive CDSS

Hazlewood and colleagues accepted the challenge, acknowledging that 'Research evidence alone cannot tell us which treatment is best for patients, and the reason is simple. Even where high-quality evidence is available, treatment choices inevitably involve trade-offs between benefits, risks, dosing, or other monitoring requirements. Incorporating patients' preferences into treatment recommendations has been viewed as the next step in guideline development, but rarely occurs in practice' [6] (p57). They argue that guideline panels should view the assessment and incorporation of *patients'* preferences as a critical step in the evidence to decision process and accordingly seek to assist these panels in making the necessary judgments when translating evidence into a recommendation, using empirically derived data.

In their application to Early Rheumatoid Arthritis (ERA) they 'estimated the preferred treatment using patients' preferences measured in a discrete-choice experiment to apply weights to benefit and harm outcomes from a network meta-analysis and other considerations (dosing, rare adverse events)... We applied this to treatment recommendations for ERA where there is disagreement over the preferred treatment. Thus, a secondary aim was to generate evidence that could be used to help inform patient-centered GRADE treatment recommendations for ERA' [6] (pp.56, 57).

Unfortunately, both the analysis and presentation of results confirm that any approach to the clinical decision through guideline recommendations, even if population-preference informed in this way, is not patient-centred. According to the authors, the patient's preferences - and decision aids - are to come into play only if the percentage of patients preferring a therapy is somewhere between 62% and 78%. Most patients would prefer triple therapy as initial treatment (78%) or after an inadequate response to methotrexate (62%). The probability of choosing triple therapy as initial treatment was further from 50% (the point of indifference) for more patients, making our prediction more confident, and suggesting a stronger recommendation could be made. After an inadequate response to methotrexate, the choice was more split, suggesting a decision aid may be helpful... [6] (p56).

Both proposals - that there is a population percentage threshold for a strong recommendation and that it is at 50% - are arguably in breach of both the reasonable patient legal standard for informed consent and simple ethical principles.

Hazlewood et al. accept that preference studies may be very context-specific, so that existing studies may not be relevant to a guideline group's target population. Hence, generating context-specific preference data would require additional effort, and that may not be feasible. Nevertheless 'Guideline developers could... use a central source of high-quality evidence and find or generate their own patient preference data applicable to their population. This would fit well with... the contemporary axiom of 'globalizing evidence, but localizing decisions'' [6] (p.64).

4. Conclusion

The difficulty of generating relevant group preference data is actually a blessing in disguise. The answer is to personalise, not localise, eliminating the irrelevant detour into group average preferences, and going direct to those of the individual patient in the clinic at the point of care. Conventional therapeutic CDSS should be abandoned, and basic and diagnostic CDSS re-labelled - and evaluated as - *Clinician Information Support Systems*. The best way for informaticians to support preference-sensitive clinical decision making is to redirect their efforts to producing the information (option performance ratings on each of the criteria) required in the Multi-Criteria Decision Analysis-based decision support tools essential for greater patient involvement and transparent preference-sensitivity.

Abstract. In this paper we present a decision support system, which has been designed and implemented on the case-based reasoning principles. Our decision support system is being implemented in tight cooperation with the cardiologist, who represents the main future users of the system. Our system enables its user to find the most similar historical cases to a new patient, suggest the most probable result of the potential coronary angiography examination and also provide various useful visualizations to the cardiologist, who is responsible for the final decision about recommending the coronary angiography or not for the new patient. The first response from the cardiologist about our system is very promising.

Keywords. Case-based reasoning, k -Nearest Neighbors, Medical diagnostics

1. Introduction

In the process of establishing an initial diagnosis of potential disease, a collection of relevant medical data can make a significant difference that enables doctors to make faster and more accurate decisions. For doctors, it is nowadays hard to consider a higher volume of data in the diagnosis procedure, or in determining the right treatment.

The diagnostics is a complicated process in which it is essential to have the right information available at the right time. For better decision making about patient diagnosis, we recommend an approach that compares existing patients with the new one and finds the most similar cases from history. This mechanism is known as Case-based reasoning (CBR) [1] which associates human reasoning with analogy. We implemented this method into an application that allows its users to reasonably compare new patients to the ones that already have their correct diagnosis. The use of CBR in the medical field is currently reviving. The knowledge base of medical knowledge is changing, and doctors have different approaches. The fact that the CBR methodology very much resembles the doctor's thinking suggests the successful use of CBR in the medical domain [7]. Cardiovascular diseases are still the leading cause of mortality not only in Slovak Republic, but in the world as well [10]. It was expected,

¹ Corresponding Author, Department of Cybernetic and Artificial Intelligence, Faculty of Electrical Engineering and Informatics, Technical University of Košice, Slovakia; E-mail: ludmila.pusztova.2@tuke.sk.

when many innovative diagnostic and therapeutic approaches were introduced, that they will be accompanied by significant improvement of this situation. In contrary, risk profile of population worsened in the course of last years. Currently available modern diagnostic devices and methods can be used for early screening of patients, thereby speeding up patient selection for eventual intervention testing and indicating effective therapy. There is an unanswered question that properly indicated and evaluated new methods could reduce further investigations that unnecessarily prolong the diagnostic time for invasive-intervention strategies.

In our approach we adopted the CBR methodology (briefly described in the following section 2), utilizing k NN method for finding the most similar cases from history in the RETRIEVE phase, but also in an original way within the REVISE phase (more detailed description of the application design is provided in section 3). An important advantage of our application is visualization. There are more types of data visualizations, among them e.g. visualizations based on Principal Components Analysis (PCA). Some of the available visualizations as well as other implementation details are described in section 4.

2. Methodology

Case-based reasoning (CBR) is a problem-solving paradigm that is recognized and well-established method of medical science today [2]. To find a solution to a new problem, people try to use their own experience from dealing with previous tasks and adapt the old answers to fit the current situation [3]. Therefore, the main principle of the CBR is the assumption that solutions to similar problems should also be similar.

The CBR process consists of four main phases [4]:

- **RETRIEVE** – finding one or several of the most similar cases to the current problem,
- **REUSE/ADAPT** – reapplying the knowledge that was gained from the found cases to solve the actual problem,
- **REVISE** – checking the correctness of the proposed solution and modifying the solution if needed,
- **RETAIN** – saving the currently solved case for potential future use.

Algorithm k -Nearest Neighbors (k NN) was used to find the most similar previous cases. It is a versatile supervised machine learning algorithm that can be applied to solve problems leading to both classification and regression tasks. Fundamentally, algorithm k NN [5] assumes that cases close to each other, utilizing some suitable metric, are similar.

3. Application design

The goal of this application is to make the best use of anonymized collected medical data about real patients with cardiovascular diseases. It will serve as a decision support system for cardiologists. The main benefit of this application lies in helping the doctors to determine diagnosis faster and more precisely. Specifically, it should assist them

while deciding whether the current patient shows signs of potential cardiovascular disease and needs more exact examination such as coronary angiography.

The CBR cycle begins with the user entering medical data about a new patient who underwent various examinations. Entering the input data triggers the search for the most similar previous cases, which represents the first phase of the CBR cycle called **RETRIEVE**. This step utilizes the calculation of standard distance metrics such as Euclidean, Manhattan or Mahalanobis distance. We considered regarding the number of similar cases to be returned, the following options: only one case, an arbitrary number from interval $<1;10>$ or all the cases that are more similar than a given threshold. In the third scenario, there could be a situation when all of the known cases would be very different than the current one which means that none of them would be retrieved. Therefore, the combination of both options seems to be the most appropriate. At the same time, we also want to provide information about the calculated similarity of the cases.

The following phase, which is known as **REUSE/ADAPT**, uses the prevailing value of the target attribute as a solution for the new case. If the suggested value indicates that the new patient has a low risk of suffering from cardiovascular disease, the CBR cycle continues to the next phase.

The third phase is called **REVISE** because of the verification of the suggested diagnosis. We implemented the following approach. The application selects ten known cases that are the most similar to the current new case for each of the existing classes (i.e. for all different values of the target attribute). The calculated distances of the nearest cases from the current patient are then summed up for each of the classes of the target attribute and the class with the lowest result is marked as a revised suggested solution. If the newly proposed solution is the same as the initially suggested diagnosis (utilizing k NN), the user can consider this solution as a more trustworthy one.

We proposed also a different approach to the adaptation phase of the CBR cycle in [6]. Our approach there is based on the comparison of stored decision rules with the new one. Different parameters of the most relevant decision rule are identified and subsequently adapted to the new case.

4. Implementation

The proposed application is being implemented in the R language with the help of the Shiny package. The application makes use of the previously collected known cases which are stored in a relational table in a “.csv” file format.

The application currently consists of five different tabs. The user can navigate between them through the menu positioned at the top of the page. The first tab is called “The New Case” (see Fig. 1) and contains the main functionality of the application. The user has to enter necessary personal information, such as year of birth and gender of the new patient, to start the process of finding similar cases and suggesting the diagnosis. The number of cases taken into account can be any number in the interval $<1;10>$ with the default setting being the number 5. The information about the current patient and similar cases can be exported via the download button and saved in a “.docx” file format.

There are also five different options concerning the type of measure used for calculation of the distance between cases:

difference between the two PCA visualizations is that in the second visualization the user can alter the number of attributes that are selected for the calculation of the PCA components.

Figure 2. “PCA - Principal Component Analysis” tab.

5. Summary

In this paper we presented an original decision support system for cardiologists, which is based on the CBR methodology. k NN algorithm is implemented both, in the RETRIEVE as well as in the REVISE phases, in each of them in a different way. Moreover, CBR cycle is supported by a set of visualizations, which have been designed in tight cooperation with the target user, a cardiologist. Based on his feedback on the first version of our system, it seems to be very useful and promising. In future work we plan to evaluate our CBR system also in a user’s study with cardiologists.

Abstract. The world population is dramatically ageing, resulting in an increase of the prevalence of older dependent adults living in nursing homes (NHs). Because of insufficient resources in NHs, and nurses' lack of time and knowledge, adverse events, most of them being preventable, are often reported. Clinical decision support systems (CDSSs) have proven to improve the quality of care in various healthcare settings such as hospitals and primary care centers. However, the use of CDSSs in NHs is still limited and little is known about their influence on nursing practices and NH residents' clinical outcomes. We conducted a scoping review of the literature to evaluate CDSS use in NHs. Out of 1,231 retrieved papers, 15 studies were retrieved which assess 10 CDSSs applied to pressure ulcers and malnutrition prevention, drug prescription, and disease management. This review showed CDSSs could be effective in NHs for improving routine clinical practice and patient outcomes, but research is still needed to implement effective CDSSs in NHs.

Keywords. Clinical decision support systems, Nursing homes, Geriatrics, Clinical Outcomes, Evaluation, Quality of care

1. Introduction

Because of the ageing population and the rise in the prevalence of dependent older adults, an increasing number of aged people currently live in nursing homes (NHs). Studies have reported that NH residents are at risk of developing adverse events, many are preventable (e.g. pressure ulcers, urinary tract infections, falls, adverse drug events) [1]. This is often explained by insufficient staff and resources in NHs, and nurses' lack of time and knowledge [2].

Electronic Health Record systems (EHRs) contain patient's data, including nursing records and care track. EHRs have proven to provide accurate, up-to-date, and

¹ Corresponding Author: Abir Abdellatif, Hôpital Charles-Foix, 7 avenue de la République, 94200 Ivry-sur-Seine, France. E-mail : abir.abdellatif@gmail.com

holistic information about patients at the point of care, enabling more coordinated and efficient care. The use of clinical decision support systems (CDSSs) connected to EHRs have demonstrated to improve the quality of care in both hospitals and primary care settings [3]. However, the use of CDSSs in NHs is still limited and little is known about their influence on nursing practices and NH residents clinical outcomes [4].

Teranga² is a French vendor of an EHR called “NETSoins” used in about 40% of NHs nationwide. One objective is to develop a CDSS connected with NETSoins to improve the knowledge of nurses and support them in providing better care to NH residents. Prior to this development, we conducted a scoping review of the literature to analyze CDSSs used in NHs and assess the key factors of these systems regarding nurse satisfaction, care process improvement, and NH residents clinical outcomes.

2. Methods

PubMed was searched between 2010 and 2019 for studies describing CDSSs used in NHs. We used a combination of MeSH terms and key words to account for the management of elderly in NHs (i.e., “Geriatrics”, “Long-Term Care”, “Nursing homes”, “Residential Facilities”, “Care homes”) and the use of CDSSs (i.e., “Decision support techniques”, “Decision support system, Management”, “Decision support system, Clinical”).

Two of the authors (AA, DN) independently selected original articles describing and evaluating the implementation and use of CDSSs in NHs on the basis of titles and abstracts. The reference list of selected papers was also examined.

Selected articles were analyzed according to (i) the specific clinical application of the CDSS, (ii) the design of the study (type, CDSS users, sample size), (iii) CDSS features (reasoning process and users’ interfaces), (iv) impact of the CDSS, and (v) CDSS users’ acceptance and adoption in routine practice beyond the intervention period. We included observational studies (OSs), randomized (RCTs), and non-randomized controlled trials (NRCTs).

3. Results

The query used to search PubMed retrieved a total of 1,231 articles leading to 26 potentially relevant publications for full-text review after the screening step. Eleven publications were excluded (CDSS was applied to primary care, no computerized CDSS was used, no outcome was assessed) leading to 15 articles [4–18] that met our criteria for review.

The 15 selected studies assessed 10 different CDSSs that were gathered for the analysis according to their clinical application: CDSSs for prevention, CDSSs for drug prescription, and CDSSs for disease management. In all the retrieved studies, users’ adoption of CDSSs in routine practice beyond the intervention study period was not well described and was finally not analyzed in this paper.

3.1. CDSSs for pressure ulcers and malnutrition prevention

We retrieved five studies [4–8] assessing the implementation of three CDSSs to support pressure ulcers and malnutrition prevention. Two studies were OSs [5,8], two were RCTs [4,7], and one was a NRCT [6]. All studies enrolled nurses and nursing aides as primary CDSS users. All CDSSs were guideline-based and used the display of alerts automatically triggered when risk assessment instruments (e.g. the Risk Assessment Pressure Scale for pressure ulcer risk screening or the Mini Nutritional Assessment scale for screening nutritional status) exceeded predefined thresholds. One CDSS [4–6] is integrated into the NH EHR, the two others [7,8] are standalone systems that need to be activated by users. One CDSS [8] is a patient monitoring system to facilitate nursing staff implementation of standard care for pressure ulcer/injury prevention. The system operates from data on frequency and position of sensors worn on each resident's anterior chest, to estimate the nursing staff compliance with repositioning standard of care, before and after visual monitors were activated to cue staff.

Globally, using the CDSS lowered significantly the prevalence of malnourished residents (reduction from 28.8 to 19.8%) [4], and pressure ulcers incidence (reduction from 15.1% to 7.1%) [7]. The three CDSSs were associated with an improvement of care processes (better compliance of nursing care with clinical practice guidelines, especially concerning NH residents repositioning, improvement of practitioners' attitude and nursing culture) [5–8]. User reviews were mixed, diversely reporting ease of use, lack of training, and resistance to computer use.

3.2. CDSSs for drug prescription: medication review and daily drug prescription

We made the difference between CDSSs supporting daily drug prescription and those for “medication reviews”. A medication review is a structured analysis and re-consideration of the entire patient's drug treatment aiming at simplifying and optimizing it, usually performed at least once a year in geriatrics by both physician and pharmacist.

Five studies [11,12,16–18] (among which four OSs and one NRCT), evaluated two CDSSs for medication review. Two studies [11,12] enrolled pharmacists as primary users of the CDSS whereas nurses were the CDSS principal users in the other studies [16–18]. Both CDSSs were guideline-based. One [11,12] is a standalone system and operates to support pharmacist review of physician orders. In case of drug mis-prescription, alerts are automatically triggered and displayed to the pharmacist who contacts the prescriber and indicates how to revise the wrong prescription. The second CDSS [16–18] is connected to the NH EHR. It criticizes drug prescriptions and alerts nurses about drug-related problems. All studies measured the effects of using the CDSS on care processes such as prescriptions and observed clinical practices compliance with guidelines, as well as interpersonal collaboration. The use of the CDSS was beneficial in all studies. Users were mostly satisfied by the CDSS except in one study [12], where they reported alert fatigue.

Three studies [13–15] (two OSs and one RCT) evaluated the implementation of three CDSSs to support daily drug prescription. The primary users of CDSSs were pharmacists in two studies [14,15], and physicians in the third study [13]. The knowledge bases of these systems are elaborated from clinical practice guidelines and expert opinion. All CDSSs display critics attached to non-compliant drug dosing or

prescription. One of the three CDSSs [9] is connected with the NH EHR and generates informative dosing messages or alerts for prescribers. The two other CDSSs are standalone systems where patient data have to be entered to obtain decision support. Warning messages are displayed to criticize physicians' prescriptions. CDSSs work with emails or phone calls between physicians and pharmacists.

CDSSs were successful in all studies to improve processes (e.g. increase of drug prescription compliance) and organizational aspects (e.g., time saving, team working). No clinical outcome was measured in any of the studies. Users of one study [13] expressed their dissatisfaction about unnecessary alerts (displayed in 50% of the cases).

3.3. CDSSs for disease management

Two studies (both were OSs) [9,10] assessed two CDSSs for disease management. The first CDSS [9] is applied to help data tracking and analysis to be used by physicians (tabular view for medications, weight-trending graph, and symptom analysis). The second CDSS [10] is applied to the management of urinary tract infections and is developed following Goal-Directed Design principles to support NH staff in differentiating urinary tract infections from asymptomatic bacteriuria, thus reducing antibiotic days.

The first CDSS [9] is connected to the NH EHR. It relies on a guideline-based knowledge base. The second CDSS [10] is a web-based application. Four information needs were identified from focus groups (guidance regarding resident assessment, communication with providers, care planning, and urine culture interpretation) and encoded in the knowledge base of the system (also including clinical practice guidelines). Both CDSSs provided educational recommendations. Both CDSS were considered useful for symptom tracking, visual information, facility of data entry, and ease of use.

4. Discussion and conclusion

Health information technology tools such as EHRs and CDSSs have proven to improve the quality of care in hospital settings. However, our literature review showed that these tools are not yet widely used in NHs despite a great number of residents and insufficient staff and resources, e.g., lack of doctors. On the last decade, only 15 papers describing the NH use of 10 different CDSSs have been retrieved. Most of the CDSSs were stand alone systems (six out of 10), this lack of interoperability being reported as being an issue in previous studies. Systems were poorly described in the retrieved papers and it was difficult to understand how they were developed (data processing, user's interfaces, etc.). For instance, we could not assess whether factors such as requiring practitioners to provide reasons when over-riding or providing advice concurrently to patients and practitioners, known to be winning factors to improve guideline compliance and care quality [3], were implemented. Only a few studies were RCTs (3 out of 15), evidencing positive clinical outcomes (significant reduction in the prevalence of malnourished residents and pressure ulcers incidence), and most of CDSSs were judged as satisfactory (ease of use, time saving, team working) even if some critics were also reported (alert fatigue). The number of health conditions addressed is currently quite limited although there is, undoubtedly, a great potential to expand CDSS applications, for instance to the management of osteoporosis or to fall

prevention. However, since elderly are more likely to experience adverse drug reactions, many studies were focused on drug prescription improvement.

Whether they are linked or not to an EHR, used by physicians, nurses, or pharmacists, generating alerts at the point of care or not, this review suggests CDSSs can be effective in NHs to improve nurses' daily practice and residents' clinical outcomes in several domains. However, more research is still needed for implementing effective CDSSs in NHs.

Abstract. Anticipating unplanned hospital readmission episodes is a safety and medico-economic issue. We compared statistics (Logistic Regression) and machine learning algorithms (Gradient Boosting, Random Forest, and Neural Network) for predicting the risk of all-cause, 30-day hospital readmission using data from the clinical data warehouse of Rennes and from other sources. The dataset included hospital stays based on the criteria of the French national methodology for the 30-day readmission rate (i.e., patients older than 18 years, geolocation, no iterative stays, and no hospitalization for palliative care), with a similar pre-processing for all algorithms. We calculated the area under the ROC curve (AUC) for 30-day readmission prediction by each model. In total, we included 259114 hospital stays, with a readmission rate of 8.8%. The AUC was 0.61 for the Logistic Regression, 0.69 for the Gradient Boosting, 0.69 for the Random Forest, and 0.62 for the Neural Network model. We obtained the best performance and reproducibility to predict readmissions with Random Forest, and found that the algorithms performed better when data came from different sources.

Keywords. Medical Informatics, Data Warehousing, Supervised Machine Learning, Patient Readmission/statistics and numerical data

1. Introduction

Controlling the proportion of unexpected readmissions is important for patient comfort and safety and represents a medico-economic issue. In 2009, the 30-day readmission rate in the United States was about 20% (13.3% to 23.2%, depending on the state [1]), and the cost of these readmissions was estimated at 17.4 billion dollars. In France, the readmission rate varies between 12% and 14%, according to the methodology [2].

To comprehensively address this problem in the context of population ageing and the increasing prevalence of chronic diseases, it is important to take into account the

¹ Corresponding Author, Thibault DHALLUIN, E-mail : Thibault.DHALLUIN@chu-rennes.fr

care pathway between hospital and primary care. Indeed, the days following the hospital discharge are at risk of adverse events [3–4], and therefore, a better communication between caregivers is essential. A systematic review highlighted that some 30-day readmission episodes are avoidable, but their proportion greatly varies partly in function of the (objective/subjective) criteria used to define such avoidability [5]. Nevertheless, the readmission rate is widely used as indicator to evaluate possible improvements in medical care.

Public health policies have been put in place to control the 30-day readmission rates in the United States [6], France, Germany and Denmark [7]. Consequently, research has been focused on developing methods to anticipate unplanned readmissions, by identifying relevant clinical indicators, and by developing predictive models to integrate these indicators.

The adoption of electronic health records (including laboratory data) represents an unprecedented source of data that must be exploited to better understand the patient care pathway, both descriptively and analytically. The emergence of automatic learning methods allows using these data to anticipate the patient trajectories. The most widespread predictive models [8–10] are based on classical statistical approaches that are widely used in medical research, such as logistic regression analysis. More recently, machine learning methods have started to be tested (e.g., Gradient Boosting, Random Forest, Neural Networks). Therefore, the contribution of each of these methods must be now assessed in similar conditions.

The goal of this study was to compare different approaches to predict the 30-day readmission risk of hospitalized patients using massive hospital and geo-demographic data.

2. Methods

The included hospital stays had an admission date that ranged from January 1, 2013 to December 31, 2018. This dataset was then partitioned into a training set (admission date before December 31, 2016) and a test set (admission date after January 1, 2017). To ensure the results comparability with the French national indicator for 30-day readmission, the selection criteria were those of the ATIH RH30 national methodology (Agence Technique de l'Information sur l'Hospitalisation - Les réhospitalisations à 30 jours) [11], except for the geolocation data that were used at the place of the geographical code. Specifically, the patients included were aged 18 years or over and received obstetrical, surgical or medical care. Patients with no geolocation in mainland France and patients in palliative care settings were excluded. Hospital stays with a different mode of entry than from home and iterative stays (chemotherapy session, radiotherapy, transplant context, renal dialysis sessions, cataract surgery) also were excluded. A readmission was defined as an unplanned hospital stay within 30 days after the end of the previous stay.

Data were extracted from the Rennes clinical data warehouse [12] that contains most of the computerized medical records, including clinical notes, drug prescriptions, laboratory test records and administrative data. All information about a patient's hospital stay was de-identified and organized in structured and unstructured data in the electronic medical record. If the patient had several hospital stays, all hospital stays were combined in a single electronic medical record. Diagnoses were coded using the French version of the International Classification of Diseases, 10th Edition (ICD-10)

that incorporates the specific French adjustments. Medical and surgical procedures were coded according to the French classification of clinical procedures (CCAM classification) [13]. Drug prescriptions were coded using the Anatomical, Therapeutic and Chemical (ATC) code. The potentially significant covariates extracted from the clinical data warehouse were: age, sex, length of stay, number of previous hospitalizations, illness severity in the French version of diagnosis-related group (DRG) classification, major diagnostic categories, medical diagnosis and comorbidities (ICD-10), medical and/or surgical procedures (CCAM), hospital department and laboratory data (still organized according to a local thesaurus).

Demographic data, aggregated at the municipal and sub-municipal level [14], were merged with the patient using the geometric map background and the corresponding geolocation: median pre-tax household income during the year, part of ≥ 15 -year-old population, education level, unemployment rate for the 15 to 64-year-old population, and socio-professional categories for the 15 to 64-year-old population.

Data handling and pre-processing were performed on R with 'tidyverse' (version 1.2.1), 'data.table' (version 1.12.2) and 'recipes' (version 0.1.6). The compared algorithms were the most frequently found in the literature: logistic regression ('stats' version 3.5.0), random forest ('randomForest' version 4.6-14), gradient boosting ('gbm' version 6.1.1), and neural network ('nnet' version 7.3-12).

The main outcome was the area under the ROC curve (AUC) and the secondary outcomes were sensitivity, specificity, positive and negative predictive value of cut-point closest to the top-left corner of ROC space. As the models did not yet have a specific use, there was no reason to focus on sensitivity (to screen for stays at risk of readmission), and specificity (to target specifically stays with readmission).

The importance of the different covariates (clinical/geo-demographic data) was assessed according to criteria adapted to each algorithm: odds ratio for logistic regression, relative influence for gradient boosting, Gini index for random forest, and Garson algorithm for neural network [15].

3. Results

Among the 410 837 stays available in the clinical data warehouse, 259114 were retained (193913 for the training set and 65201 for the test set) based on the inclusion and non-inclusion criteria. The main non-inclusion criteria were patients younger than 18 years (76670 stays excluded), absence of geolocation (18454 stays excluded), iterative stays (14477 stays excluded), and palliative care (5750 stays excluded). The 30-day readmission rate was 8.8%. Readmitted patients were on average 4 years older than non-readmitted patients, and with a higher proportion of males (58.3% versus 49.2%). Demographic data were comparable in readmitted and non-readmitted patients.

The AUC was 0.61 for logistic regression, 0.69 for gradient boosting, 0.69 for random forest, and 0.62 for neural networks (Figure 1). Logistic regression and gradient boosting placed the most importance on post-emergency units, number of iterative hospitalizations, disease severity (DRG classification) and co-morbidities. The regression model became robust by adding a stepwise cross-validation. Random forest focused on other variables, including demographic data. In addition, random forest gave the most robust results, regardless of data sharing, with constant performance and use of covariates.

Table 1. Main characteristics of the patients of the included stays.

Readmission	YES	NO
N	22893	236221
Age (mean (sd))	60.30 (19.34)	56.46 (20.67)
Sex, male (%)	13355 (58.3)	116329 (49.2)
Length of stay (mean (sd))	6.18 (10.47)	4.81 (8.14)
Number of previous stays (mean (sd))	2.58 (3.27)	1.82 (1.85)
Median pre-tax household income (mean (sd))	20654.29 (3274.12)	20643.86 (3210.86)
Higher degree rate (mean (sd))	0.30 (0.13)	0.30 (0.13)
Unemployment rate (mean (sd))	0.12 (0.06)	0.12 (0.06)

Table 2. Prediction performances.

Algorithm	TP	TN	FP	FN	Se	Sp	PPV	NPV	AUC
Logistic Regression	3011	37187	22325	2678	0.53	0.62	0.12	0.93	0.61
Gradient Boosting	3531	39065	20447	2158	0.62	0.66	0.15	0.95	0.69
Random Forest	3528	39075	20437	2161	0.62	0.66	0.15	0.95	0.69
Neural Network	3467	33911	25601	2222	0.61	0.57	0.12	0.94	0.62

Figure 1. ROC curve.

4. Discussion

This is the first comparison of 30-day predictive readmission models in France using clinical data warehouse and geo-demographic data. In addition, this study used a methodology as similar as possible to the definition of the French national 30-day readmission indicator, while taking advantage of data from different sources.

There is a wide literature on the subject of 30-day hospital readmission prediction models. The AUC values of our prediction models are comparable to the 0.71 found in the literature [8]. The community state of health, healthcare delivery/access, hospital management, computerization of departments, data integration, and advancement of the data warehouse are among the many factors that affect the results of the obtained models. The inclusion criteria and the choice to focus on all-cause readmissions also

influence the prediction model performance. Indeed, the algorithm used is an end-of-chain parameter that depends very strongly on the learning data quality.

5. Conclusion

In conclusion, the predictive models displayed comparable performances (AUC from 0.61 to 0.69). Random forest showed the best and most reproducible performance compared with the other models. The importance of the included variables differs among models and merging external data can improve their performance.

Abstract. This paper proposes an approach and demonstrates its application for cross-border exchange of clinical documents oriented towards the use of archetype concepts and international patient summary standards adopted in the European Union. A novelty in this approach is the management of native XML instances of an archetype concept in the CEN 13606 standard by means of a native XML database and XML technologies. The computer experiments demonstrate that it is suitable for representing relatively small clinical datasets such as those describing rare diseases like the Acromegaly illness, where the semantic context in the relatively small number of symptoms is practicable to tag in terms of SNOMED-CT terminology codes. Additionally, we demonstrate that the semantically enriched information model can facilitate secondary use of clinical data by visualizing the execution of queries based on standard terminologies. Finally, the compatibility of the information model with the IPS standard enables sharing of clinical data among different information models.

Keywords. international patient summary, semantic interoperability, CEN 13606 archetype, e-health, rare disease register, native XML database, terminology

1. Introduction

European citizens enjoy a variety of rights when it comes to intra-EU mobility, including the right to seek care in another Member State. Health systems in the European Union aim to provide high-quality, cost-effective care. Directive 2011/24/EU on patients' rights in cross-border healthcare describes patients' right to receive health treatment, including planned procedures, in another Member State (MS) and to then get reimbursed domestically up to the level that would have been covered by their home State [1].

The realization of the full potential of the Directive's provisions is still in development. In March 2017, the Commission launched the European Reference Networks (ERNs), creating cross-border virtual networks of healthcare providers across the EU to tackle rare diseases and conditions [2]. The ERNs are supported by Clinical Patient Management System (CPMS) in providing knowledge and resources for

¹ Corresponding Author: email: dimitardt@gmail.com

improving the diagnosis and treatment of rare or low prevalence complex diseases [3]. CPMS establishes a common ground for collaboration between healthcare professionals in this subject area allowing them to upload patient cases in Rare Disease (RD) registers and share this way diagnosis, care and treatment procedures. However, only a Digital Imaging and Communications in Medicine (DICOM) Viewer for image consultations and a couple of IHE profiles for connection with Hospital Information Systems are provided, no other European or International standards for data exchange are implemented. A Central Metadata Repository (ERDRI.mdr) is established in 2019 in order to ensure semantic interoperability between existing RD registries [4]. It stores all data elements (metadata) used by the participating registries, including the names of the data elements (designations) and their definitions. Authorized users can create groups of hierarchical structures of new data elements in a limited number of languages (English, German, Spanish and French). This good principle of containerization is not related to any standard approved in the European Union like the CEN 13606 standard, where the reference model is composed of hierarchical structures. Moreover, the content of data elements may be represented with minor exceptions in an arbitrary way without a reference to external ontologies, terminologies or standards. This complicates substantially the exchange of data between European databases and national RD registers.

The situation requires prompt and adequate solutions really helping the clinicians to exchange clinical information without wasting time to translate and transcribe the already registered medical records. In our point of view the clinical data sets for several rare diseases that were accumulated in the last decades as part of existing national registries are suitable to start the data exchange, maintaining the clinical context. These datasets are structured clinical records and include several important variables [5]. Their exchange using European health informatics standards between existing European data bases and National RD registries can foster the way for implementation of semantic interoperability.

The objective of this study is to prove that the CEN 13606 Standard for Electronic Record Communication based on the Archetype paradigm and the International Patient Summary (IPS) together with the appropriate international nomenclatures and classifications successfully could provide a high degree of semantic interoperability. In the following section we present the methods we employ to achieve this objective. The results from computer experiments are discussed in Section 3 and the conclusions are outlined in Section 4.

2. Methods

In this paper we present an approach and demonstrate its application for cross-border exchange of pseudonymized clinical records between the Bulgarian Acromegaly register and the Liege acromegaly survey (LAS) database that aggregates the data from 14 European RD registries [6]. This approach is oriented towards the use of archetype CEN 13606 concepts and maintenance of compatibility with the International Patient Summary (IPS) described in the preliminary standard (FprEN 17269 [7]) and the technical specification (FprCEN/TS 17288 [8]).

International nomenclatures like SNOMED CT, LOINC, ICD 10 and ATC are used in the CEN 13606 Archetypes. A mapping is performed between the clinical concepts existing in the national databases and the respective codes in these nomenclatures for laboratory tests, procedures, diagnoses and medications. This allows to design an

archetype of the RD dataset compatible with the IPS standard enriched with semantic context (Fig. 1-left side) and describe it using the Archetype Description Language in CEN 13606. Unlike existing approaches that employ archetypes with relational databases we obtain a native XML instance of the obtained archetype(Fig. 1-right side). We refer to this XML instance as native because it is valid with respect to the CEN 13606 Reference model [9]. It allows us to represent RD datasets in terms of such instances with native XML database like existDB [10] and execute queries on the such archetype instances with XML technologies. Note, that an archetype query language is not provided as part of the CEN 13606 standard.

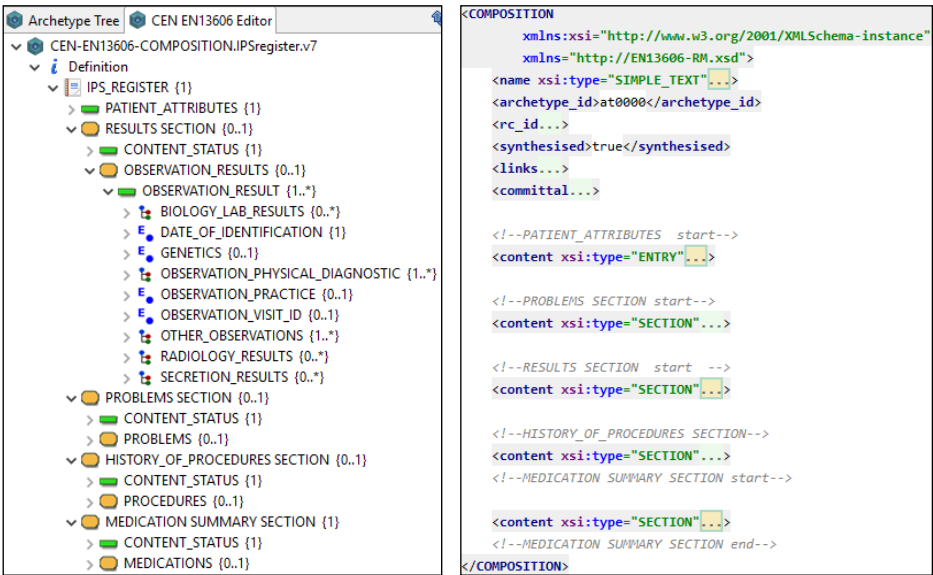

Figure 1. CEN 13606 Archetype of IPS sections(left) and its corresponding native XML instance (right).

3. Results

The methods described in the previous section have been applied to develop a client server web application with the NoSQL database existDB [10]. A dataset with real clinical data from the Bulgarian Acromegaly register is loaded as a “collection” of XML documents in this database. Each one of these documents is a native XML instance of the archetype shown in Fig.1. The client makes use of the web graphical interface on Fig.2 to create new native XML instances of the archetype and add data content in these instances. For example, Fig. 2 shows the recorded clinical data for symptoms observed during the Acromegaly therapy of a given Patient, where the semantic context is represented by SNOMED-CT codes [11].

The web application makes use of RESTful web services allowing the client to manage the collection of XML documents on existDB. It enables cross- border exchange of RD datasets for example, with the Liege acromegaly survey (LAS) database. Once the XML document is complete it can be uploaded in the LAS database. Moreover, this standard- based approach allows to query the RD dataset and visualize the results. For example, Fig. 3 shows visualization from two of the major Acromegaly symptoms during

the Acromegaly therapy of the selected Patient. This visualization allows us to conclude that therapy has been successful, and the Patient has fully recovered.

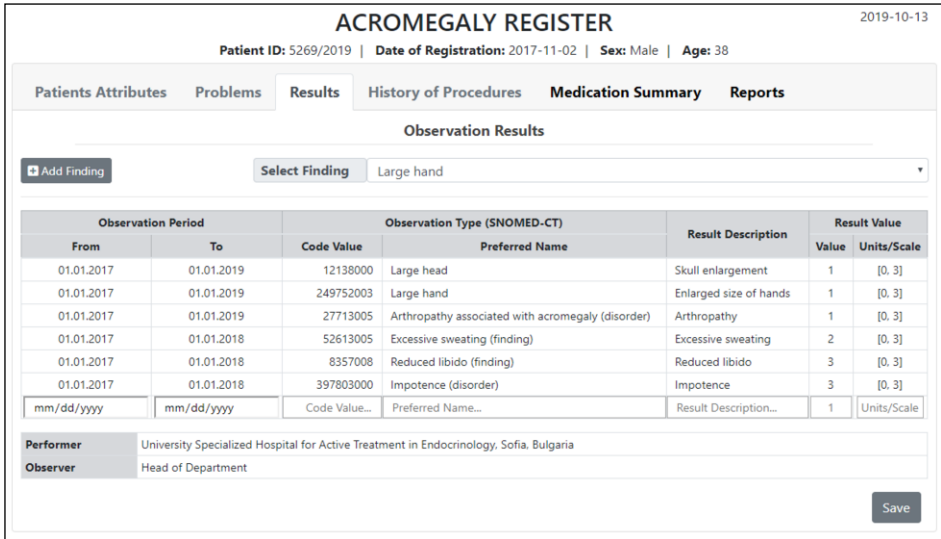

Figure 2. Web interface for management of XML instances of the IPS archetype.

Figure 3. Visualization of selected clinical data for Acromegaly Symptoms.

4. Conclusion

In this paper we have proposed an approach and discussed the results of its software implementation for cross- border exchange of clinical data for rare diseases like the Acromegaly illness. The implementation of the proposed approach employs EN 13606

archetypes to build a model of a clinical document compatible with the recently proposed IPS standard FprEN 17269. The novelty in this approach is the creation of a native XML instance of a CEN 13606 archetype concept representing a clinical document model in terms of the Archetype Description Language. It allows to achieve semantic interoperability in exchange of RD data sets compatible with the IPS standard by means of native XML databases and XML technologies. The computer experiments show that this approach and its implementation are quite suitable for representing relatively small clinical datasets such as those describing rare diseases. For example, the semantic context in the limited number of symptoms in the Acromegaly Register is practicable to tag with SNOMED-CT terminology codes. Additionally, we demonstrate that the semantically enriched information model can facilitate secondary use of clinical data by visualizing the execution of queries based on standard terminologies. Finally, the compatibility of the information model with the IPS standard enables sharing of clinical data among different information models.

Data Transfer Model for HIS and Developers Opinions in Turkey

Filiz ISLEYEN ^{a,1}, M. Mahir ULGU ^a

^a *T.C. Ministry of Health, General Directorate of Health Information Systems,
Ankara, Turkey*

Abstract. Hospital Information Systems (HIS) are used in every hospital in our country and these systems have been developed by different vendors. If there is a change in the HIS software used in a hospital for various reasons, all data must be transferred from the current HIS to the new HIS. Accurate, complete, consistent, reliable and rapid transfer of this transfer is important in order not to interrupt the health care provided by the hospital. The aim of this study is to introduce a data transfer model standart (VEM) between independent HISs and to explain the validations that are applied to enforce the model work correctly. In addition, we share the opinions from HIS vendors who develop VEM compatible systems. In the development process of the model, studies with data transfer experts from the HIS vendors in Turkey were performed. A validation software has been developed to check the compatibility of VEM with HIS software. In addition, a questionnaire was sent to HIS developers via e-mail and their opinions on VEM were received. Fourty six HIS developers voluntarily participated in the study, and 70% said they thought VEM helped with solving data transmission problems. As a result, it can be said that VEM has been successful in solving many problems encountered for data exchange in HIS changes in hospitals.

Keywords: Data transfer model, data exchange, HIS.

1. Introduction

In our country and in the world, hospitals, which are the users of Hospital Information System (HIS), could change the system they are using, for the reasons of the negative elements of the important components (modules), usability problems, dissatisfaction, etc. In such cases, hospital managers should prepare for a difficult transition and set realistic expectations [1]. Implementing a new Electronic Health Record (EHR) or switching to another is likely one of the most disruptive predictable events a hospital can experience, affecting practically every employee and workflow at a hospital [2]. Conceptually, most HIS operate on the same type of information (demographics medical history, medications, diagnosis, laboratory findings, billing, etc.). Since medical content standards of HIS were not determined when they were first used in hospitals, most of the HIS' in Turkey have formed their own specific terminology for

¹ Corresponding Author, email: filiz.isleyen@gmail.com

medical data. This unstandardized terminology also was making it difficult to transfer data accurately and quickly in the HIS data transfer process. It may be a tremendous challenge to understand and map the database architecture used in the current HIS to transfer the health history of each patient to a new HIS. Mapping of data at a high level of accuracy, a fully automated transfer while taking into account all the patient information in the hospital is not a big problem in only our country, but also in the world [3]. Accurate mapping of the data into the new system is vital because EHRs serve as the legal health record, containing individually identifiable information describing the healthcare services delivered during a patient's clinic visit [4]. The process of transition from current HIS to new HIS can lead to long, exhausting efforts and data loss [5].

In our country, as the databases to be transferred are different in every HIS and the data transfer process is completed in a longer period than it is anticipated. If there were a universal standard (or at least some kind of "universal translator" for EHR data), data conversion would be much simpler, and the process of switching EHRs would be easier [6]. Given the differences in HIS structures and the diversity of EHRs across countries, it may be premature to speak of a universal model for data transmission. However, a national model independent of the HIS structure may be successful for the data transfer problem. For this reason, a data model has been developed for data transfer and studies have been carried out to use this model as a standard in data transfer between HISs. Minimum Data Transfer Model (VEM) has been developed to be the model that defines the structure and minimum content of any HIS. The minimum here; expresses the data that need to be transferred to the new HIS as a priority.

The aim of this study is to introduce a data transfer model standart (VEM) between independent HISs and to explain the validations that are applied to enforce the model work correctly. In addition, we share the opinions from HIS vendors who develop VEM compatible systems.

2. Method

The model, which was developed as a standard for the use of HIS data transfers, was created by analyzing the database designs of HIS softwares used in the majority of the state hospitals in Turkey. The main purpose was to determine a minimum data transfer model which would cover necessary data elements and which should be able to be transferred primarily between HISs. In this context, a draft model is formed by working together with HIS vendors. VEM is designed as arelational structureusing relational database views. These standard views are created by HIS vendors and reflect the records from the original HIS database. HIS vendors have to follow VEM standards and provide VEM compatible views (HIS-VEM) according to their database design. Because HIS vendors can adopt various software development pattern they are free to desing their own relational database models however they have to provide VEM views on each HIS database system. In some occasions vendors use multiple primary data tables to create certain views and in some occasions VEM to physical database mapping would be one to one. VEM views content is available as

XML at <https://vem.saglik.gov.tr/>. According to the validations made so far, two update studies have been done for VEM. In the first version, the number of views was 63, while in the current version it is 84. All versions of VEM are available at the reference web site.

A validation software (VEM Analysis Program - VAP) has been developed to test the compatibility of VEM with HIS software. VAP was developed using the Delphi programming language in RAD Studio platform and it supports all of the databases (Oracle, MySQL, MsSQL, PostgreSQL etc.) used by HIS software in our country. HIS vendors are required to login to the VAP where they run the database connection information which they use to test the HIS-VEM data transfer model. VAP checks if the data structure and content which are found as XML in <https://vem.saglik.gov.tr/> are compatible with HIS-VEM.

It was seen that the validation process of the each HIS vendors via VAP was taking a long time. For this reason, a workshop was conducted in order to enable HIS developers to work with each other. In the workshop, HIS vendors were paired to work with another HIS vendor which was using same database system. For example, a vendor using Oracle has been paired with a vendor using Oracle. A test form was given to the software developers and they were able to work together for five days by analyzing each other's HIS-VEM views by analyzing the problems that might occur in case of data transfer.

During the HIS-VEM validation, the HIS developers who form the model expressed their opinions on VEM views in written form or verbally. However, in order to get the opinions of the developers who could not give face-to-face interviews because they were busy or they could not join the workshop, a web-based questionnaire was sent to 56 HIS developers via e-mail.

3. Results

The validation process via VAP is done in two steps. In the first step; the views of VEM, which is the standard model and HIS-VEM are compared (data elements in the view, reference codes of the view, SQL script information, comparing the number of records in the view etc.). In the second step; controls related to the quality of the data in the views (PK-Primary Key Control, Reference Table Name Control, Relational Data Control, Time Accuracy Control, Data Accuracy Control, Data Type Control) are performed.

Majority of the HIS vendors tested their VEM compability using the VAP system, however, they all failed the tests initially. Later, we had organized a workshop in which all HIS vendors were invited to attend and at the end of the workshop most the HIS vendors participating to the workshop made successful implementation of standard VEM in to their system and they manage to get compliance with our standards.

A web-based questionnaire was prepared using a 5-point Likert-type scale and sent to 56 HIS developers. Forty-six of them responded. 41 of the participants were male, 5 were female and 94% were university graduates or higher. Their work experience was 12 ± 5 years (mean \pm standard deviation) and the highest working

time was 23 years. 96% of the participants knew about the VEM standard and 91% of them said that they know how to transfer data in the hospitals where they work. The responses of the participants regarding VEM views are shown in Table 1.

Table 1. Opinions of HIS Developers about VEM

Considering the entire systematics generated for VEM, please express your opinion about the following statements.					
Questions	Certainly Disagree (1) n (%)	Disagree (2) n (%)	Undecided (3) n (%)	Agree (4) n (%)	Certainly Agree (5) n (%)
I think that the number of views created in VEM is adequate for the purpose of the developed model.	4 (%8.7)	5 (%10.9)	8 (%17.4)	22 (%47.8)	7 (%15.2)
Views are sufficient to meet field requirements.	3 (%6.5)	7 (%15.2)	12 (%26.1)	14 (%30.4)	10 (%21.7)
I think the explanations of the created views are clear and understandable.	4 (%8.7)	5 (%10.9)	8 (%17.4)	18 (%39.1)	11 (%23.9)
VEM helps to solve problems with data transmission.	3 (%6.5)	4 (%8.7)	7 (%15.2)	15 (%32.6)	17 (%37)
With VEM, it is easier to collect data from the field.	1 (%2.2)	6 (%13)	5 (%10.9)	19 (%41.3)	15 (%32.6)

4. Discussion

Changing HIS can create a host of issues. These include practical issues, such as the sheer amount of time required to research, implement, and transition to a new HIS package; loss of productivity in the process; and changes in functionality from one HIS to another, which require retraining and perhaps may lead to a loss of some functions on which the physicians counted previously [6]. Patient demographics, billing, and other financial data that was stored in the previous HIS will need to be transferred to the new HIS [6]. When the HIS changes in Europe and the United States are examined, it can be seen that the HIS exchange takes a long time and a large part of this period is related to the data transfer part. When the proposed strategies to conclude the changes in electronic health record in the easiest way are examined, it is seen that the importance of using standard terminology of different HISs is emphasized [3].

The developed model has been used by various HIS companies in data transfer since 2015 in Turkey. The aim of the model is to determine the data (patient information, laboratory results, diagnostic information, etc.) that should be transferred in order to prevent disruption of the health care processes in the hospitals in order to ensure that these data are transferred accurately, completely and consistently. Therefore, the model is named as the minimum data model. The feedback received from the HIS developers using the model has shown that VEM has been successful in

data that needs to be transferred primarily. However, when all the data in the hospital need to be transferred from the existing HIS to the new HIS, it was seen that the HIS developers use traditional methods in addition to VEM. This necessitated the transfer process to be performed in two different ways and caused the HIS developers to perform two separate tasks. According to our experience of VEM validation study or feedbacks from HIS developers using the model, it was seen that the developed model-VEM gave faster results compared to the traditional method, but a model that would provide all the data to be transferred in a hospital would be more beneficial. For this reason, new studies have been planned to improve the scope of the VEM.

Due to the success of many HIS vendors in our workshop, workshops create an effective learning environment for HIS developers. We also believe that the collaboration of HIS developers and their successful results increased the adoption of VEM.

In Table 1, 70% of respondents responded positively to the question “VEM helps to solve data transfer problems, 15% stated that they did not agree and 15% stated that they were undecided. The majority of the participants think that the model is successful compared to the traditional method.

Although VEM is a standard that was developed for data transfer, it has been learned that most HIS software developers have made changes to their database structure after VEM. It is considered that VEM shows a positive effect on data standardization.

5. Conclusion

As a result, the majority of HIS developers stated that VEM solves the problems in data transfer. In light of this information, it can be said that the model developed to be used as a standard in HIS changes in hospitals has been successful for the targeted aim. This fact also revealed the necessity of extending the model to a wider spectrum of the data in any hospital. By expanding the VEM, data transfer processes in hospitals in our country can be completed more quickly and smoothly.

Decision Quality Is a Preference-Sensitive Formative Concept: How Do Some Existing Measures Compare?

Jack DOWIE^{ab1}, Mette Kjer KALTOFT^b,

^{ab}*London School of Hygiene and Tropical Medicine, UK*

^b*University of Southern Denmark, Denmark*

Abstract. The primary output of a decision making process is a decision and a key outcome measure is therefore decision quality. However, being a formative construct, ‘decision quality’ is both preference- and context-sensitive and legitimate alternative measures accordingly exist. A decision maker wishing to measure decision quality in the evaluation of a decision or decision making process needs to be aware of the attributes of the measures on offer. This paper establishes some of the key conceptual differences by examining two measures: Decision Quality Instruments and MyDecisionQuality. Four of their main conceptual differences relate to: the timing of the measurement (at the point of decision or at follow-up when the ‘downstream’ outcome is known); (whether or not an objective assessment of the information state of the individual is included (as opposed to self-reported state); whether the instrument itself is preference-sensitive; and whether the measure is to be used in the context of individualised clinical practice at the point of care or only in research to produce group level feedback. Establishing agreed measures of decision quality is necessary and useful, so long as it is accepted that it is a preference- and context-sensitive construct, in the way that is widely acknowledged in relation to, for example, Health-Related Quality of Life, with its many measures.

Keywords: decision quality, Decision Quality Instruments, MyDecisionQuality, formative construct, preference-sensitive.

1. Introduction

If the fundamental aim of informatics is to help decision makers make high-quality decisions, it might be expected that the measurement of ‘decision quality’ would be a major focus of interest. However, there is limited attention to this *outcome* in the literature, compared to the amount devoted to related *input* qualities: the quality of the information inputs being produced, the quality of the transmission and dissemination of information inputs, and the quality of the processing of the information inputs within decision making. In this paper we explore two specific approaches to the measurement of decision quality, an exploration which, while restricted in scope, is sufficient to throw significant light on the reasons for this relative paucity of attention. Among other things, it may help explain the surprising non-appearance of decision quality as a

¹ Corresponding author: Jack Dowie, LSHTM, 15-17 Tavistock Place, London, UK WC1H 9SH; email: jack.dowie@lshtm.ac.uk

Patient-Outcome Measure (PROM). In the comprehensive 2015 survey of the latter [1], the term ‘decision quality’ appears only within the section headed ‘Patient experience’ and not as a PROM.

Among the underlying reasons for this marginalisation is that the latent unobservable construct (‘decision quality’) is a *formative*, not a *reflective* construct, and therefore preference- and context-sensitive [2]. This has both methodological and practical consequences. Among the methodological consequences are the psychometric standards appropriate for validating instruments seeking to measure it. ‘Decision quality’ is an ‘it’ that does not exist in the sense that a reflective construct (such as appendicitis) exists, where psychometric standards such as internal consistency are valid. The main practical consequence of its formative nature is that there are many possible and acceptable definitions of decision quality, none of which can be validated as the ‘gold standard’. The ambition to develop a universally agreed definition of a formative construct is understandable since widely-agreed definitions have their uses and in many senses are essential. The various formative measures of Health-Related Quality of Life exemplify acceptance of their intersubjective, value-based provenance. However, capitalising a construct as Shared Decision Making or Decision Quality cannot produce ontological transformation from formative to reflective, even if it is sometimes institutionally convenient to treat it as if it does.

There are many meaningful distinctions which can and should be made between different proposed measures of decision quality, and the basic point being made here is that the *decision* on which measure of decision quality to select for use, from a set of alternative measures given this label, is both *preference-sensitive* and *context-sensitive*. *Different instruments will measure different constructs and are not to be regarded as different measures of the same construct.*

A decision maker selecting the measure that is optimal for the particular evaluation they are undertaking needs to be informed about their content and construct validity. The limited aim here is to establish *some* of the key *conceptual* differences in measures of decision quality. We set aside most practical differences, the need for alternative versions or adaptations for contexts such as low literacy or ethnicity being taken for granted. Examining two measures will be sufficient for our limited purpose: the Decision Quality Instruments (DQIs) [3-4] and MyDecisionQuality (MDQ) [5-6]. The concept is often used implicitly as an umbrella for a set of individual indicators [7].

2. The Decision Quality Instruments (DQIs)

A generic DQI framework is used in the production of condition-specific instruments, 14 of which are currently available, including ones for breast cancer surgery, prostate cancer screening and treatment, back pain and knee and hip osteoarthritis. (<https://mghdecisionsciences.org/tools-training/decision-quality-instruments/>)

Since the DQIs are condition-specific, we will focus on that for Breast Cancer Surgery (BCS-DQI) [3-4]. The BCS-DQI comprises a set of 15 ‘objective’ knowledge questions ‘to determine whether patients are informed’ and a set of 8 questions about their ‘goals and concerns’. As a profile measure, it produces two scores. The *DQI-Knowledge Score* is the number of correct responses divided by the number of items, resulting in scores from 0% to 100%. A threshold for considering a patient to be ‘well-informed’ is set, using (if available) the mean knowledge score for a group of patients who have viewed a decision aid. The *DQI-Concordance Score* measures ‘the extent to

which patients received treatments that reflected what is most important to them'. It is derived from a multivariate logistic regression model in which the treatment received (e.g. surgery vs. non-surgical) is the dependent variable. The goals and concerns specified by the respondent are the independent variables, with other factors that should influence treatments (e.g. stage of disease for breast cancer surgery) included, as needed. The dependent variable is a predicted probability of treatment for each patient. Patients with a predicted probability of more than 50% who had the treatment, and those with a predicted probability equal to or less than 50% who did not have the treatment, are classified as having treatments that match their goals and are 'concordant'. (Dividing the number who matched by the total number in the sample then yields a summary percentage concordance score for the group.) A binary *Decision Quality Composite Score* can be created with a score of 1 for patients who were well-informed [i.e. met the pass threshold] and received treatments matching their preferences, and 0 for all others.

The interpretation of both the 2-score profile and the binary composite score is only at the group level and available only after follow-up, months after the decision. So the DQIs are essentially research tools for evaluating a decision process (which is assumed to be 'shared decision making', usually including a decision aid), for the purpose of improving future practice through group level feedback. They are not envisaged as tools to be used as the source of individual feedback in real time within clinical practice.

3. MyDecisionQuality (MDQ)

MDQ is a preference-sensitive instrument in which individuals provide their responses as soon as possible after a decision is made. The responses are of two distinct types - their personal ratings of the preceding decision- and decision-making process on 8 criteria, and their weightings for those 8 criteria. The MDQ score is the weighted sum of the ratings (i.e. the expected value for each option). The abbreviated labels for the 8 items are four which relate to the decision content - Options, Effects, Criterion Importance, and Effect Chances - and four which relate to the decision process - Trust, Support, Control, and Commitment [5-6].

MDQ is a self-reported, preference-sensitive ('dually personalised') multi-criterial index, generic across both conditions and contexts. Its primary purpose is to evaluate the quality of a decision and decision process and do so at the individual level. The evaluation is to occur as soon as possible after the decision is taken. This is to rule out reference to any downstream outcomes, for whatever reason. (Two common ones are to establish whether action or behaviour subsequent to the decision was in accordance with the person's expressed 'goals and values' and to permit their *experienced* regret to affect the assessment of decision quality.) It also excludes 'objective knowledge possession' as a criterion. However, it addresses both the decision and the decision process, being designed to indicate whether the 'reasonable patient' legal standard for *informed and preference-based* consent has been met (items 1-4), as well as the 'subjective patient' ethical standard for the care process (items 5-8). Where clinicians agree to complete an equivalent measure, it can provide decomposed measures of concordance (e.g. between patient and practitioner) and so establish which ratings or weightings are the source of any discordance. A sub-analysis indicates the criteria which hold the greatest potential for improved future decision quality. It is possible to

aggregate MDQ scores across individuals and arms of trials [8], but the interpretation of these results must be approached with caution, given their individual preference-sensitivity.

4. Discussion

A wide variety of constructs of decision quality are possible, with the main distinctions resting on *why* they are done, *who* is asked to provide *which* type of responses/s to *what* items, and *when* and *where* they are asked to do so. The answers determine whether the measure of decision quality is preference-sensitive in relation to the items in the instrument; whether the measure is useful in real time clinical practice or is essentially an output from evaluation research at a group level; and whether it is appropriate in evaluations of a decision, of a decision process, or a decision aid (including policy makers and regulators approving the last of these).

The timing of measurement is perhaps most important, because for many it impinges on the validity of the measure, as well as its use. Elwyn and Miron-Shatz report the widespread view that 'Good (or bad) decisions may have good or bad outcomes by virtue of chance, at the level of individual consequences.... post hoc assessments, based on the outcomes of decisions, are unsafe measures of good decisions.' [9] (p141-2). Delayed assessment also permits regret to enter into any evaluation at 'downstream' follow-up. *Experienced* regret - indeed all hindsight - is a valuable input into a future decision, but only if it is not allowed to affect the evaluation of a previous one, in which one has had the opportunity to input *anticipated* regret, in foresight. Dissonance reduction is another post hoc influence on evaluations of decision quality widely regarded as undesirable.

Incorporation of an objective knowledge test is a further example of how a different construct of decision quality is created. Decision makers in some contexts may prefer a measure reflecting responses from 'objectively informed persons'. Others will reject this: '... knowledge as a necessary component of a good decision - both as an evaluation of the effectiveness of deliberation and as an evaluation of the determined decision - may be difficult to operationalize and, at a deeper level, may reflect an untested assumption - that a standardized, pre-specified level of knowledge is necessary in order to achieve a high level of deliberation.' [9] (p144).

5. Conclusion

Since the latent construct of decision quality is formative, each of these instruments measures the construct it measures. An instrument should be chosen for use in an evaluation if its characteristics are preferred and it is context-relevant, as deemed by the decision maker. Ambitions to produce a standardised, preference- and context-free decision quality assessment instrument should be resisted, with the different products accepted as a menu from which a preference- and context-sensitive selection can be made. We note that it is claimed that the definition of decision quality in DQIs has been validated by the International Patient Decision Aid Standards group [4,10]. While this establishes its serious credentials as a construction of decision quality, as with any formative construct these rest on the intersubjective agreement about its contents (items and weightings), reflecting the beliefs and preferences of the producing group. MDQ

does not seek to answer the philosophical question of what constitutes a ‘good decision’ [11], merely to provide a measure of ‘decision quality’ with its particular set of characteristics. Decision quality should be regarded as *the* fundamental outcome of a decision making process, despite the challenges its formative character presents.

Funding

The software used in current implementations of MDQ was installed at <https://ale.rsyd.dk> in a nationally funded project to develop decision support tools. SATS J.nr.1-1010/116/27.

Conflict of Interest

Jack Dowie has a financial interest in the commercial use of the Annalisa software.

Defining the Contextual Problem List

John MEREDITH^{a,1}, Ian MCNICOLL^b, Nik WHITEHEAD^c, Kemi ADEMOYE^c

^a *Wales Institute for Digital Information, Cardiff UK*

^b *OpenEHR International, London UK*

^c *University of Wales Trinity Saint David, Swansea UK*

Abstract. The Problem Oriented Medical Record (POMR) is considered a key charting method to support clinical care. Although not uniformly represented amongst digital health systems, this paper presents a clinical model to represent multiple clinical perspectives from a single problem list. The contextual problem list model is defined according to primary diagnosis, comorbidities and problems arising from the primary condition. It is represented within the patient record as a single composition according to the prescribed context. The model pattern could help alleviate the traditional criticisms of paper and digitally based problem records.

Keywords. Contextual problem list, problem oriented medical record, problem list, clinical models, digital health, electronic health records.

1. Introduction

Health records are traditionally ordered into individual data silos such as pathology, medications or radiology. One such silo, the problem list is represented within the digital domain with variable degree of functionality[1] despite the rules of the concept being well understood[2]. Medical care pathways are traditionally arranged to support the management of multiple problems in the primary care setting through to secondary care via a range of diagnostic procedures[3]. This iterative process achieves a more granular focus with increasingly detailed problems for specific conditions such as diabetes.

The Welsh Information Solution for Diabetes Management (WISDM) is being developed as part of a national digital platform. It is *by definition* a problem oriented medical record (POMR). Its specification describes functions to support the curation of a problem list according whether an entry is a complication of the primary disease, or other important comorbidity that may affect ongoing treatment. This paper describes a clinical model for a contextual problem list (CPL) as a persistent composition within the electronic health record (EHR) to support this requirement.

2. Background

As suggested by Dr Lawrence Weed, there is a need to align the patient record according to the problem[4]. Since the first computerised systems began to appear there has been great variability in how the problem list manifests in the (EHR). Merely replicating paper-based processes and transposing them to the digital domain are not sufficient.

¹ John Meredith, E-mail: john.meredith@wales.nhs.uk.

Manual curation of a list is inherently burdensome and data quality impacts how likely it is to be used and updated[5]. The rules on what should or should not be included in the problem list are less clear[6]. As a result, the problem list as a component of the wider digital record has been shown to not always be available or necessarily complete[7,8].

Disadvantages of the POMR include emphasis of when problems manifest opposed to their priority, and the repetitious nature of their structure[9]. The effect of “compartmentalisation” in inhibiting the “synthesis” of multiple problems and the additional risk of substantiating a differential or incorrect diagnosis as the clinical truth is also cited[10]. POMR can be seen as a barrier to the patient narrative through the propagation of increasingly granular but clinically similar problems[1]. This is further complicated by the need for different views depending on clinical perspective or role and the nature of problems being recurrent[11]. Despite this, the problem list is a persistent function within many modern EHR systems.

Weed[4] originally envisaged his chart as a flat list of entries marked as active or inactive with nested variants where appropriate. This juxtaposed the common pattern found within secondary care reporting or outpatient letters of primary problem/ diagnosis with comorbidities. The latter focused on a single problem or care pathway while the Weed POMR takes a more holistic approach.

Grouping individual entries as a diagnosis or comorbidity is key for billing and the attribution of expended resource. However, it might be postulated that it provides direct clinical value in prioritising and focussing a set of complex clinical issues around the presented problem (and perhaps more so than a POMR styled list). We therefore present the pattern defined within this paper for the CPL as a hybrid of both approaches.

3. Definitions

Within the context of this research, a “problem” may be a presenting complaint or confirmed diagnosis. The nature of the CPL means that the following definitions are inherently flexible and individual records may exist within any given category depending on the clinical perspective and may change over time. As a result, the underlying model needs to support the ability to refute, dispute and replace individual entries and for those changes to be clear and visible within the patient record. Utilising coded entries derived from a terminology service is preferred although this represents a point of note for implementers to observe and is not mandatory.

Primary diagnosis represents the condition for which the patient is receiving care and frames the clinical context of the CPL. While the primary diagnosis may be a variation of a range of entries, these should be limited to a specific care pathway (in this case diabetes). It is possible to initiate a CPL without a primary diagnosis being present as the context itself is categorised within the associated metadata of the composition.

Co-morbidity is a coded diagnosis that does not require management or direct acknowledgment by clinicians within a specified disease domain. However, it is of clinical importance to the ongoing care of the specific disease context. It can be assumed that comorbidity entries will be actively managed through alternate care pathways, but they are compatible with the underlying information model for primary diagnosis.

Problems and complication records represent a diverse range of entries. They may contain a clinical problem that has arisen from the primary diagnosis, is being investigated as a result of the problem or is a keynote for the clinician to consider such as a recent bereavement or learning disability. Disease complications will require active

management by the clinician and maybe the result of referrals from other care settings. Entries within this section may reside from clinical findings (e.g. a presenting complaint of pedal oedema) or disease related disorders (e.g. diabetic retinopathy).

The final category concerns entries that may derive from a variety of findings or disorders, but are not of direct concern or relate to the context instantiated with the CPL. However, these records cannot be ignored as they may become important in future. Consideration must be given by the clinician to reconcile entries from a variety of sources.

The approach defined here means that a diabetologist may be treating a patient with some form of diabetes and record a primary diagnosis of Type I diabetes mellitus with peripheral angiopathy. Conversely, a renal physician could be treating a patient with a primary diagnosis of chronic kidney disease. Both primary diagnoses are dependent on the clinical context, and in some cases may be linked if one disorder is predicated by the other (e.g. chronic kidney disease due to type 2 diabetes mellitus). Both entries are also suitable for inclusion under the comorbidity heading of their respective CPL.

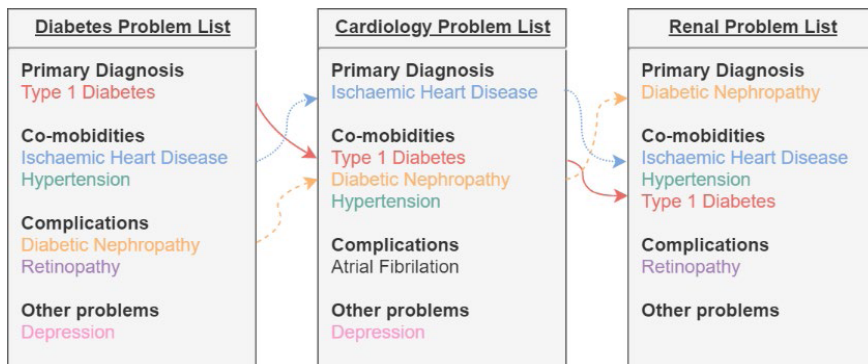

Figure 1. Shared problem records within three contextual problem lists.

A diagnosis of “diabetic nephropathy” may be considered a complication of the patient’s primary diagnosis of Type I Diabetes i.e. this condition would not have occurred had the patient not had this primary diagnosis. However, this could also be considered the primary diagnosis for a nephrologist (Figure 1).

3.1. Model Development

The CPL was modelled with openEHR Archetype Designer[12]. Figure 2 describes the applied model pattern. Each context category is embedded within the relevant section with additional attributes from problem/diagnostic qualifier to support, barring the “Other problem”. This is to ensure that the pattern cannot be disrupted through incorrect attribution of problem categories within the “Other Problem” section.

Additional data elements have been included to support the wider provenance of the CPL including an absence statement that describes why the list may be empty. For example, a patient early on the diagnostic pathway may be considered to have a finding of pre-diabetes. It may not be appropriate to record this as a primary diagnosis although it is still a condition of note. A recorded entry that there are “no known problems” or “no primary diagnosis” is a potentially valuable statement of fact for a patient at this stage.

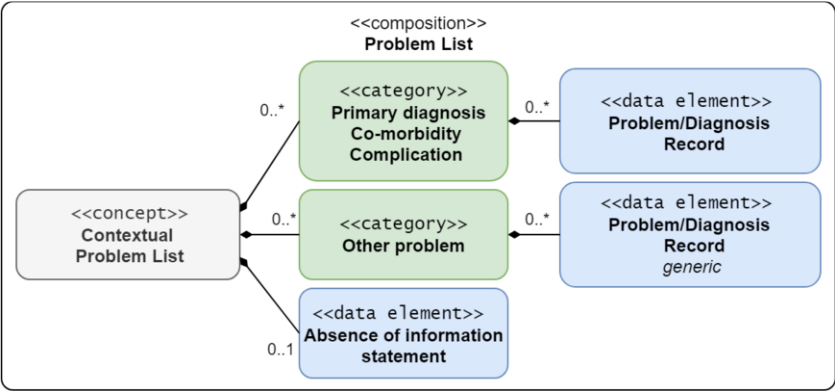

Figure 2. Information model for the contextual problem list template. Each category is optional.

4. Discussion

While the criticisms of POMR are legitimate when concerned with paper, digital functionality can support or eliminate many of them. Duplication of data, a concern in the paper domain[2], is mediated where a digital repository is able to act as a single source of truth. Orientation of the record around the problem, as Weed suggested, is key to facilitating benefits such as more thorough and increasingly relevant medical charts with faster information retrieval[1]. By utilising the CPL as a digital composition, it is possible to view a problem list with a specific clinical perspective such as diabetes as well as a master list of all other problem records. This master list is considered a core component of the EHR[13].

The design of the CPL outlined here seeks to simplify the wider requirement for a single instance of the POMR by creating individual compositions that relate to specific problems or conditions. This is analogous to the “index concept” approach[14]. The level of granularity is focussed upon a primary condition and the many subproblems that may be present with complex cases.

Where accuracy of the problem list is high, clinical errors can be reduced and patient safety increased [15]. This pattern facilitates multiple actors in the clinical pathway to create, review and update problems using data that is recorded once but shared widely. Data quality is of specific concern if we are to rely on the digital record. There is evidence that completeness of data is encouraged when alerting functions are presented to the user[16]. It has been suggested that there are benefits for sharing the POMR in cases of chronic disease management spanning multiple care domains[17]. In addition, this defines a basis from where algorithm-based care can be provided via well defined, standards-based data models.

5. Conclusion

The proposed method for representing the CPL can support multiple care domains from within a single data repository. It represents a hybrid of the traditional POMR and context specific records. While not a definitive list of all patient problems, it presents the key issues that are of concern for the management of the patient’s condition at a point in time.

Individual entries within a CPL may be recorded by other clinicians and considered of interest by other clinical specialties for inclusion in their own contextual problem lists.

Digital Follow-Up Application for Cancer Patients – Value Mechanisms Regarding Health Professionals’ Work

Sauli MIETTINEN^a and Henni TENHUNEN^{a,1}

^a*Institute of Healthcare Engineering, Management and Architecture (HEMA Institute),
Department of Industrial Engineering and Management, Aalto University, Espoo,
Finland*

Abstract. This study examined the value mechanisms of a digital cancer follow-up application (CFUA). Value is defined as the health outcomes achieved per resources used. The focus was on how the digital health intervention (DHI) affects the professionals’ work. The research was conducted through interviews of healthcare professionals in the empirical context of gynecological cancer clinic at a university hospital in Finland. The identified key mechanisms were improved coordination and optimized care level. The CFUA improves coordination through reducing time restrictions of work, as the professionals have more chances to time their contacts and plan their work. The CFUA helps in optimizing care level, as the application can effectively filter patients to either nurses or physicians according to symptoms. Coordination mechanism is closely connected to other healthcare value mechanisms, such as reducing waste and supply management. This study increases understanding of DHI value potential recognition, and how value can be actualized.

Keywords. Telemedicine, Cancer Care, Value-Based Healthcare

1. Introduction

Introducing new digital health interventions (DHIs) requires that their cost-effectiveness, their value, is proven. Implementing DHIs with demonstrated value improves the economic sustainability of the healthcare system and benefits all parties, including patients, payers, providers and suppliers [1]. Porter defines value as the patient health outcomes relative to the costs of care for the patient [1].

Cancer care DHIs have been a subject for academic research. It has been found that digital interventions can through certain mechanisms help cancer patients to cope better with the disease and symptoms [2]. Patient-reported-outcome follow-up has been shown to improve cancer patients’ survival and quality of life [3,4]. According to [5], telemedicine in cancer care can reduce the travel costs for patients and thus improve total value. Web-based outcome surveillance was found to be a cost-efficient way of monitoring and can reduce the follow-up costs for the insurance-provider [6]. It has been stated that also the staff viewpoint should be considered in digital services in cancer care [7]. Thus, when analyzing an intervention’s potential for improving value-based healthcare, it is important to examine the personnel perspective, where a

¹ Corresponding Author: E-mail: henni.tenhunen@aalto.fi

significant part of the costs are incurred. Therefore, this research took intervention's impact on healthcare professionals' work as the focus and aimed to find the mechanisms that cause changes in their behavior and affect costs.

The studied DHI is a modular digital cancer follow-up application (CFUA) called Kaiku Health. This study focuses on the use of CFUA for gynecological cancer patients. The context of the CFUA case is the gynecology unit of a tertiary hospital in Finland. In the unit, all types of gynecological cancers are treated. CFUA is used both during treatments and in monitoring after treatments. The people using CFUA include patients, specialist physicians and nurses, some of which work with patients during cancer treatments, and some with patients in monitoring after treatments. All specialist physicians are specialized in gynaecology, and their tasks include diagnosis and treatment of gynecological cancer patients. Most of the patients are over 65 years old. The patients use CFUA to report their health status and symptoms by filling symptoms and quality of life questionnaires and can contact healthcare personnel through CFUA with chat messages. The message feature also allows sharing files, such as medical certificates. When a member of the personnel logs in, CFUA shows the patient cases that have new information that should be handled. Healthcare professionals react to the contacts either through CFUA or in acute situations by phone (Figure 1).

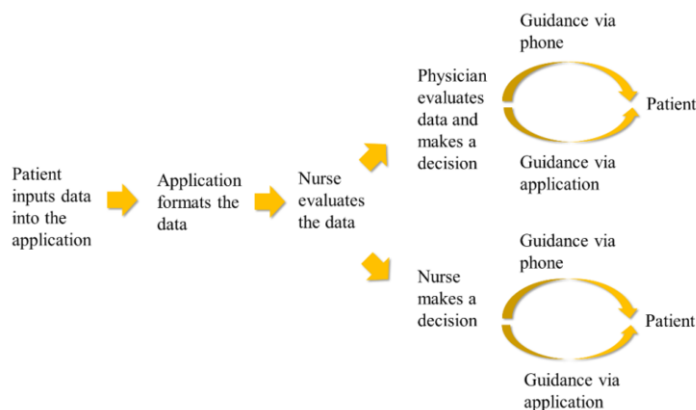

Figure 1. Typical data flows in the use of CFUA.

The application works with mobile devices and desktop devices. CFUA is offered as a separate installation for every customer clinic [7]. In WHO's (2018) classification of digital health interventions, CFUA can be described as a telemedicine intervention including e.g. consultations between remote client and healthcare provider, and remote health monitoring [8]. CFUA also possesses features of personal health tracking interventions, as it allows self-monitoring of health in form of symptom data.

The objective of this study was to identify and analyze the mechanisms through which CFUA creates value in cancer care from the healthcare professionals' perspective in the context of tertiary gynecological cancer clinic. The research problem was approached using the CIMO logic, describing the context, intervention and outcomes to analyze the mechanisms [9,10]. CFUA's CIMO-configuration and the changes were examined. We posed the following research question: How does a digital follow-up application change the work of healthcare professionals and which value mechanisms are activated through these changes?

2. Data and Methods

This research was conducted as a single case study. The unit of analysis was the work of a healthcare professional, which comprises tasks, actions and work processes, as processes can be complemented with other units of analysis, especially when they are not always clearly manifested [11]. The data was collected through semi-structured interviews with eight members of the clinic’s healthcare professionals (N=8). Four informants were specialist physicians and four informants were registered nurses. Three of the nurses worked with patients during the cancer treatments and one nurse worked with patients after the treatments (Table 1). The interview data was transcribed verbatim, and sorted into categories.

Table 1. List of informants.

ID	Role in Organization and Cancer Treatments
Nurse 1	Works with patients in active treatment
Nurse 2	Works with patients in diagnostics and monitoring
Nurse 3	
Nurse 4	Works with patients in active treatment
Physician 1	Specialist, diagnostics and treatment of gynaecological cancers
Physician 2	
Physician 3	
Physician 4	

The data collected from the interviews was analyzed qualitatively, using the Grounded Theory methodology. From the data, core categories were formed that described the relevant themes summarizing the data set [12].

3. Results

The identified value mechanisms were improved coordination, right care delivery level and timing, reduction of waste, demand/supply-management, control information and health co-creation through symptom-based care (Table 2). Especially the mechanism of coordination comprises sub-mechanisms, such as reduced variation and is connected to other mechanisms.

Having more accurate and exact data about the patient enables optimizing the care level. CFUA provides data about the patients’ symptoms, which is used to decide whether a physician or nurse should handle the case. Nurses first read the non-urgent CFUA contacts, and only forward them to the physicians if necessary. This allows a more efficient care level, as doctors only handle more challenging cases fitting their skills.

Variation in tasks hinders productivity, as mental preparation and adaptation are needed when changing between tasks. The health professionals argued that they are able to follow their schedules better with CFUA, as the unpredictable phone calls do not interrupt and interfere with their current work. CFUA allows scheduling the day into sub-parts where the focus stays on a certain type of task for a longer period of time. Reduced time dependency allows the professionals to perform tasks with more efficient scheduling. The coordination mechanism of CFUA is primarily connected to organizing patient care and delivery of services in a timely manner. Instead of facilitating the organization of cancer care in a system level between teams and providers, CFUA is a tool for coordinating cancer care between the patient and specific nurses and physicians assigned to the patient.

Table 2. Value mechanisms of the CFUA.

Mechanism	Summary
Coordination	CFUA allows individual professionals to work more flexibly and plan their work better, reducing interruptions and improving productivity.
Right timing (for personnel)	With CFUA, the professionals have a time-window that allows them to choose a suitable time to handle a contact.
Care delivery level	CFUA allows optimizing care delivery to the lowest level by directing only the most challenging contacts to physicians.
Reduction in waste	As CFUA reduces interruptions in professionals' work, they need to spend less time.
Control information	CFUA provides more complete information, such as time series of symptoms, to professionals. This information helps professionals to decide what they should do next, thus improving coordination of care.
Demand/supply management	By relieving the time restriction of communication, CFUA allows scheduling the supply, the answers to contacts, more flexibly.
Symptom-based care	Patients contribute to their care by actively monitoring and reporting their health status. With reduced routine appointments, the professionals focus more on providing care for patients who report symptoms.

Improved control information can lead to a more optimal processing as the right decision can be made. The professionals using CFUA stated that the time-series of the patients' earlier symptoms help in comparing the situation with previous weeks, and thus evaluating if further actions are needed. Reducing waste "Muda" happens when improved coordination of work reduces non-value adding tasks. In addition to providing more data about patients, the CFUA can also provide more structure to monitoring processes. With CFUA, the processes can potentially be more standardized, if the contacts are more predictable. On the other hand, any lack of clarity in the procedures of CFUA use can cause waste.

In addition to the CFUA, the demand in the clinic is actualized through two channels: phone calls (scheduled and non-scheduled) and clinic visits. Although the timing of demand remains roughly the same, the channel of demand is connected to the timing of supply. In phone calls, the professionals must answer when a patient calls, whereas for CFUA contacts they have up to two days' time to answer. Supply can be planned in a more flexible way, while still retaining sufficient patient experience, as the patients are instructed not to use CFUA for urgent matters. The mechanism of demand/supply-management is related to the coordination mechanism. The ability to time supply with a larger degree of freedom allows better coordination of work, both in individual professional and organization levels. Similar to coordination, this mechanism is enabled by removing or reducing the time-restrictions of professionals' work.

Routine clinic visits can be economically inefficient when the personnel spends time examining patients that do not have any symptoms. With CFUA, the professionals mostly contact patients that have reported significant symptoms. Symptom-based care is connected to the co-creation of health. In co-creation of health, the patient contributes to maintaining or improving their state of health. The co-creation of health mechanism functions also through managing demand.

4. Discussion and Conclusions

This study identified several mechanisms through which CFUA increases value. The mechanisms were analyzed from the healthcare professionals' perspective, and most of the identified mechanisms create value by improving the productivity of the

professionals. The mechanisms affecting efficiency and productivity include both mechanisms improving individual professionals' efficiency in tasks, as well as mechanisms that allow more efficient allocation of tasks between professionals. The implementation and organizational practices seem to have a strong effect on the value creation of digital follow-up applications. The digital application should be an integral part of the professionals' work, with clear roles and procedures for using it. The primary source of value of digital application is the data output that creates or improves information. Incomplete movement of information in an organization deteriorates the value created. Key challenges that digital interventions could solve in healthcare are coordination and integration of fragmented knowledge. In the studied empirical context, CFUA has the potential to improve coordination in multiple ways.

The findings of this study contribute to the development of value-based healthcare and to the evaluation of digital health interventions. The study also has certain limitations. We did not interview the patients. Therefore, the value creation was analyzed focusing on costs rather than health outcomes. However, changes in professionals' work have effects on health outcomes, if the patient work changes. Patient outcomes also affect costs, as quick recovery incurs less costs than prolonged treatment. Furthermore, the actualization of the mechanisms as outcomes or costs was not measured. Nevertheless, this research has identified intermediate outcomes that could be used as measures for the value of digital interventions and for confirming the mechanisms in future research.

Digital Technology Trends Supporting Assisted Independent Living of Ageing Population

Anthony MAEDER¹

College of Nursing & Health Sciences, Flinders University, Adelaide, Australia

Abstract. The paper provides a narrative overview of trends in digital technology related innovations for supporting ageing subjects to live independently with assistance, synthesized from selected scoping reviews and informed by subsequent analysis of peer reviewed literature appearing in the past 10 years. Four categories of trends are identified: assistive and supportive technologies; monitoring devices and systems; communications and connection technologies; and intelligent health information systems. For each of these categories, a synthesis commentary and illustrative examples are provided, concluding with a summary discussion on future directions.

Keywords. Ageing, assistive technologies, digital health, health services

Introduction

Technology for supporting ageing well and care provision for ageing subjects has traditionally been seen as providing additional capabilities to those supplied by human carers [1]. Their potential can be realized through consideration of appropriate alignments between technologies, users and care settings [2]. Three major categories of health purpose for this type of technology-based independent living assistance can be distinguished: enabling personal and social interactions; help with daily living activities; and as a means for delivering clinical services [3]. Recently, use of specific digitally-driven technologies to support ageing subjects in various supported situations has become increasingly adopted [4]. Examples of well-established digital technology for ageing subjects include devices to supplement body functions (e.g. hearing, heart function, diabetes medication), systems for monitoring health conditions (e.g. vital signs, physical activities, mental and sleep states), and services for enabling health and wellbeing interactions (e.g. videoconferencing, online health portals, self-care management apps).

The concept of using technology as a channel for implementing new models of care in ageing has been predominantly based on the notion that it is desirable that the care be provided in non-traditional delivery settings, such as the subject's home [5]. This view leads quite naturally to the interpretation of the role of digital technologies in new models of care in ageing as enabling care delivery to be performed remotely (in location and timing), and with the augmentation of remotely collected information and remote interaction and communication mechanisms [6]. For example, it is recognised that remote patient monitoring offers a sound approach for management of chronic diseases [7], and that remote clinician-patient interactions are suitable for a range of specific clinical tasks [8]. It is also acknowledged that various implementation challenges [9] and adoption barriers [10] exist for these approaches.

¹ Corresponding author: Email: anthony.maeder@flinders.edu.au

1. General Model

There is no apparent standardized nor widely accepted categorization of ageing health-related digital technology areas which can be followed in discussions of associated innovations. Recent literature reviews in the field have tended to aggregate many different application areas rather than conform to a defined structure (e.g. [11], [12]). Attempts to define a universal framework or taxonomy are frustrated by the huge volume and numerous variations in technology types, many having been developed as engineering exercises in non-clinical settings. A recent categorization based on contemporary technology development activities [13] suggested seven clusters: Robotics, General ITC, Sensor technology, Telemedicine, Medication dispenser and Video games. These are somewhat imbalanced for broad scoping purposes, as they vary between highly generic and highly specific topics.

Instead we will align our discussion with four areas of technology usage which are associated with broad types of care purpose, from the perspective of subjects-of-care, and so are distinctive in their orientations of access to or provision of care within the Ageing care ecosystem. These four areas were synthesized initially from a collection of widely-cited scoping reviews and categorization discussions such as those abovementioned. These sources were identified by expert consensus, as an initial step in a more extensive ethnographic analysis of references extracted by structured searching of peer reviewed literature appearing in the past 10 years as reported in detail in [14]. We did not include use of digital technology for business management and non-healthcare operations delivery (e.g. roster scheduling), nor technology used routinely for clinical process support (e.g. patient record systems).

For each of these four areas, we briefly summarize some apparent trends in the recent work related to major use cases, indicative of the overall directions that the field is following. These use cases were chosen due to their high prevalence in literature on ageing and technology and are not necessarily exhaustive, but may be regarded as dominant. We contend that these areas are major “promising directions” in digital technology trends supporting assisted independent living of the ageing population, and can be expected to have a strong impact on the successful implementation of new models of care and health in ageing. The four identified areas are:

- Assistive and supportive technologies which provide physical or cognitive aids to activities undertaken by a subject-of-care as an adjunct component of the activity.
- Monitoring devices and systems which measure and analyze personal health characteristics of a subject.
- Communications/connection technologies allowing a subject-of-care to interact with health carers remotely.
- Intelligent health information systems which empower subjects-of-care to access information and exercise informed control on their health circumstances.

2. Emerging Trends

We next provide commentary on the trends observed for these above four areas, as discerned in our literature survey, including some illustrative examples.

2.1. Assistive and Supportive Technologies

A common need for the elderly is *assistance in mobility* to overcome ambulatory limitations (e.g. wheelchairs). Digital technologies incorporated in mobility devices may be simple such as instrumented canes or frames or may incorporate more sophisticated mechanisms such as motion surfaces, limb supplementation and balance enhancement, depending on the mobility purpose and needs. An important related area is the detection and prevention of falling, which

is often a consequence of compromised mobility and potentially tractable through measurement and prediction. The use of Smartphones for mobility information collection and analysis could offer an easier pathway to delivery. The possibility that routine home care activities could be conducted by an autonomous device such as a robotic assistant has become a popular view, suggesting an appropriate form of generic technology to assist ageing in place.

Decline of *auditory and visual sensory functions* which enable interaction with surroundings cause limitations for older adults, typically addressed through external solutions such as hearing aids. The alternative of internally fitted smart devices such as the cochlear implant is now also established. Progress on augmenting or replicating loss of vision by more sophisticated technology solutions has been slower due to highly challenging neurological mechanisms at the three main sites of intervention: retina, optic nerve and visual cortex. Cognitive decline including loss of memory, balance, location and situational awareness, logical reasoning or understanding of context, through to pathological brain ageing or mental diseases, has been a popular target for technology-based approaches. A range of technology options have been identified, from computer-based sensor-controlled living environments to communication systems enabling involvement of carers in times of need. This approach is sensitive to the specific nature of the cognitive impairment and associated behaviours.

2.2. Monitoring Devices and Systems

Healthy ageing support through digital technology applies measurement and feedback on aspects of healthy lifestyle habits, physiological status, and preventive practices to assist subjects to manage and maintain their condition. This is generally achieved through use of wearable monitoring devices which collect data on variables appropriate to the subject's health circumstances. Other devices can be used to measure physiological quantities or signals which in conjunction with movement information, can allow prediction or detection of adverse circumstances e.g. falling, or cardiac events. A more comprehensive use can be the tracking of performance of conventional daily living activities or the remote observation of individuals by health service providers. Beyond activity tracking, numerous wearable devices for vital signs are also available. It is recognised that there is widespread potential for activity tracking for aged subjects in particular. Future devices may adopt IoT technology enabling greater chance of compatibility and redeployment.

Management of health conditions of individuals (such as chronic diseases) can be conducted outside of clinical environments, using measurement devices located on the subject or in their living spaces which communicate data to a remote clinical decision support system or a clinician. Devices to conduct this telemonitoring function include single and multiple vital signs loggers, heart and brain signal capture, and patient contributed inputs such as alarm buttons. They can also be incorporated into standalone integrated platforms or workstations, which aggregate data locally and provide some limited feedback and analysis to the subject, while communicating and remaining under control of a central clinical agency. The workstation may be used according to a fixed regime (e.g. daily) or when the subject feels it necessary (e.g. if experiencing symptoms). Alternatively multiple devices can be combined in a single portable or wearable system with inbuilt data communication and collection capability, often implemented as body area networks. Incorporation of mobile technologies in this setting offers an easier alternative to integration but is reliant on telecommunications infrastructure. There is argument for a more integrated approach to the future design of such systems to allow for their easier repurposing or extension, for different health conditions.

Ambient Assisted Living (AAL) environments are sensor-equipped and computer-managed living spaces which automatically observe and respond via messages and alerts to health status indicators of their aged and potentially frail or disabled occupants: this concept is also styled as "Health Smart Homes". Target areas for wider application in aged living

include health and environmental monitoring, and providing companionship, social communication and recreation/entertainment. Concerns on ethics of AAL for observing individuals closely and continuously raise issues on privacy and trust, and more generally for user acceptance in health IoT settings. A practical open issue is how large volumes of data generated by such uses can be efficiently and reliably processed by “big data” methodologies.

2.3. Communications/Connection Technologies

In a service environment where person-centred ageing care approaches are becoming more widespread, *telehealth* in various forms offers a natural technology-based mechanism for enabling new model of care solutions. For example, an appraisal of potential expanded usage of telehealth services in UK based on the “Whole Systems Demonstrator” project has suggested that this is a favourable environment for achieving integrated care. Allowing delivery of care by remote clinicians through teleconsultations and teleprocedures is a major component of this area. Another area which has benefited from embracing this approach has been chronic condition management. It has been noted that adoption and acceptance of home telehealth depends on the sensitivity with which the service is delivered, especially regarding the level of support given to subjects and their active involvement. These models also depend on dedicated service elements such as concierge in shared living facilities, or callcentres for broader scale community aged care, and on other appropriate technology solutions which are designed to support users sympathetically with their needs and abilities.

The ability of a computer to substitute for the role of a human is a compelling approach when health tasks are sufficiently simple that human delivery is a waste of resource. A *conversational agent* is a computer program which interacts conversationally (by text or speech) with a subject and is able to satisfy the expectations of the user and the service being delivered: chatbots and avatars are common examples. These have begun to see use in health applications which entail routine human verbal interaction such as self-report observations or medication reminders, with potential in mental health and dementia. Agents for use in satisfying health needs for ageing subjects require particular conversational structures to be effective, and may need to be tuned or adaptive to cater for differences between user preferences and capabilities to ensure effectiveness and acceptability.

2.4. Intelligent Health Information Systems

The trend for *individuals seeking information* about their health condition to make use of Internet sources has accelerated and in general has become an expectation in primary health care where patient-centred activities are preferred. Recently there has been a move to provide websites where information on particular areas of health need (e.g. cancer, diabetes, end-of-life) is aggregated and a compendium of background explanations, guide to clinical; evidence, resources for self-help or group support, and links to external resources are provided. There is a view that the practice by subjects of extending and embedding their knowledge of their health conditions and health histories provides a lifelong mechanism for better engagement, with an implication that ageing individuals who have already developed familiarity with such an approach can benefit from it in their years of declining health. Online sources of information on health conditions can be enhanced with material to support management of conditions and activate patient involvement in their care, and so improve patient outcomes.

Use of technology can provide value in supporting *care delivered in non-clinical settings* which are served by a variety of carers (implied by the last three areas above) in care coordination, telehealth services, and data-driven quality of care monitoring. These aspects of service delivery must be considered in the context of the need for services and the ecosystem which influences their delivery. It has been recognised that using technology to

move the focus of control to the subject can be effective: for example, cooperation by the individual in remote monitoring of chronic disease and behavior change, or in making use of mobile apps to take responsibility for their day to day health care needs.

3. Concluding Discussion

Across the four identified categories there is much commonality in many of the technology components. The use of sensors and wearable devices, and the associated use of smartphones and networked/IoT environments, is a repeated theme. A need exists therefore to ensure that these components can be easily integrated and interconnected, requiring progress in the area of standardization of protocols and data management. Much of the commentary on evolution of new digital technology solutions raises issues related to adoption and compliance, with associated ethical or social imperatives. Development of digital technology solutions in harmony with user expectations and preferences, taking into account limitations on digital literacy and usability for ageing subjects, is essential for creating successful products. While much progress has been made in conventional areas of health informatics such as electronic health record systems, addressing the needs of ageing citizens has generally been less popular. This has been due in part to design challenges across diverse stakeholder groups, and due to adoption reluctance by health services strongly reliant on human-based delivery mechanisms. If digital technology is seen as a means to enable new models of care and improve quality and equity of access, there is potential to accelerate new solution developments in this sector.

^a*Health Information Management and Statistics Office, Ministry of Health, Buenos Aires City, Argentina*

^b*Health Information Systems Office, Ministry of Health, Buenos Aires City, Argentina*

Abstract. This paper describes how an Electronic Health Records (EHR) allowed for the implementation of a strategy to reduce maternal and child morbidity and mortality in outpatient settings of hospitals in the public healthcare system of Buenos Aires City.

Keywords. Electronic Health Records, Prenatal Care, Continuity of Patient Care

1. Introduction

Every day around 830 women die from preventable or treatable causes related to pregnancy or childbirth [1]. In 2016, dealing with unacceptably high maternal mortality indicators, the World Health Organization (WHO) published new recommendations to improve the quality of prenatal care in order to reduce the risk of prenatal deaths and pregnancy complications and increase the probability of a positive outcome for both mother and child. The new model changed maternal and fetal evaluations from four to eight to increase the detection and prevention of complications during pregnancy, childbirth, or puerperium. The identification of biological and psychosocial risk factors allows to provide guidance to pregnant patients on her and her child's health care. This also promotes healthy habits and behaviors by decreasing the probability of prenatal deaths [2].

While in high-income countries the majority of women receive the recommended number of medical visits, 60% of women face the opposite scenario in low-income countries, registering more than half of the world's maternal mortality in sub-Saharan Africa and almost one third in South Asia [1]. Other research warn of the disadvantages of pregnant patients in rural areas in terms of prenatal care and the increased risk of maternal mortality, with their identification to remove barriers to access health systems and guarantee continuity of care being a major challenge [3-5].

1 Ivan Recalde ; E-mail: ivanrecalde@buenosaires.gob.ar .

In Buenos Aires City, 27% of registered pregnancies do not access enough prenatal care appointments and 5% have not had contact with the system until delivery [6]. To improve the number of prenatal care appointments in pregnant patients, the Ministry of Health designed a program called “Camino Verde de la Embarazada”. This was based on the improvement of access to comprehensive care of pregnant patients for an early identification of those conditions or determinants that may endanger the life of the pregnant patients, the fetus, or the newborn. This line of care consists of the recruitment of pregnant patients and in the active search by the primary healthcare (PHC) teams of those patients who are absent on scheduled prenatal care appointments to ensure the performance of the recommended prenatal care.

The program was initially implemented gradually in PHC centers with paper records. It was possible because they work with PHC teams alongside the community. This fact facilitated the early recruitment and monitoring of pregnant patients in its population. Subsequently, the implementation of the program scaled up to the outpatient setting of hospitals. The greatest issue with the implementation in these institutions were the huge amount of patients in comparison to PHC centers, the lack of a process that confirms consultations, and the complications registering them on paper implies. It was difficult to achieve the program, which could only be completed in a hospital, due to the allocation of human resources destined exclusively for this task. The objective of this article is to describe how an EHR allowed a strategy that reduced maternal and child morbi-mortality in outpatient settings of hospitals in the public healthcare system of Buenos Aires City.

2. Methods

2.1. Setting

The public healthcare system of Buenos Aires City is made up of an Ministry of Health, hospitals, and PHC centers structured in program areas in charge of a geo-referenced population. The main objective is to create an integrated network of care, strengthening PHC and more than 200 healthcare teams that provide to the community outside the centers and guarantee access to the system. Since June 2016, an EHR is being gradually implemented in the outpatient setting and as of September 2019, 78 healthcare centers are using EHR with a total of 4,984,680 health records across the health system [7].

2.2. Study Design

This is a descriptive study of how an EHR allowed for the implementation of a strategy to reduce maternal and child morbi-mortality in hospitals of Buenos Aires City. To accomplish this, the project leaders of the Office of Health Information Systems measured pregnant patients' health care processes, flow and registration of information, use of EHR, absenteeism registration in the outpatient offices of four hospitals, by conducting observations and field interviews. With the analysis of the data collected, various alternatives were designed for the registration and output of absenteeism data of pregnant patients on scheduled visits in obstetric outpatient clinics in hospitals, as well as their implementation strategy.

3. Results

The implementation of the “Camino Verde de la Embarazada” program in hospitals included the following aspects:

3.1. *Basic agreement between parties of interest*

Before starting the implementation, a meeting was organized with all those involved: the Ministry of Health team, project leaders of the Office of Information Systems, the heads of external offices, obstetrics office, program areas and PHC centers corresponding to the area as well as the local coordinator of the EHR implementation. The objective was to communicate the guidelines of the program and to agree upon the strategy of its implementation. Then, the schedules related to maternal and child care consultations were obtained, which involved a manual reviewing process in each of the health centers.

3.2. *General Guidelines*

The healthcare network of pregnant patients is organized according to the complexity of each case, with PHC centers being responsible for low-risk prenatal care and directing the attention of high-risk pregnancies to hospitals. The record of patients' absenteeism is carried out by health professionals, using a functionality of the EHR where they can view the list of patients with consultations scheduled and, if necessary, register missed appointments. It also allows them to register gestational age.

3.3. *Automated Report*

An algorithm in the programming language R [8] was developed for the identification of patients who were absent from arranged consultations in the obstetric schedules. Seeking to improve the filter and increase the identification of absent patients, the free text field associated with consultations based on regular expressions was used in addition to the absenteeism functionality, which also recover gestational age. Out of the absent patients identified, the algorithm consumed the Master Patient Index to obtain their basic and contact information. From this, each patient was associated with their corresponding health center under their geographic area, using georeferencing tools.

The report is automatically produced on a weekly basis on a cloud platform mounted on an internal Buenos Aires City government server, which can only be accessed through an authentication process. This protects the confidentiality of sensitive data included in the report. It is composed of the following data: hospital, date, id number, name and surname, date of birth, telephone number, email, address, appointments schedules, gestational age, and corresponding PHC center.

3.4. *Articulation of different levels of attention*

The Ministry of Health team visualizes absenteeism reports from all hospitals. They are responsible for sharing the list of patients and their contact information with program areas. Then, each program area transmits this information to their respective PHC centers. If the patient's address corresponds to other jurisdictions, the team connects the

coordinators of the PHC centers to that corresponding jurisdiction. Once PHC teams receive the information, they will attempt to contact the patient after using gestational age to rank cases, where they can reschedule a consultation in a PHC center or in a hospital according to the complexity of the case.

3.5. Implementation strategy

A pilot test was conducted in the hospital where the program was already working. The solution implemented coexisted with its usual circuit based on paper records, to contrast with the operation of the data output. Once it was found that there was an overlap between both reports, the paper circuit was abandoned and the implementation of the new circuit in other hospitals began gradually (Figure 1).

Figure 1. Evolution of the number of daily absent patients identified including nine hospitals of the public healthcare network of Buenos Aires City. The orange dotted line indicates when the new data circuit was implemented in all the hospitals.

4. Discussion

Childhood maternal morbi-mortality rates integrate key indicators of a population's healthcare level and are widely used as measures to represent the effectiveness of a country's health care system. They are constantly used to analyze and monitor the etiologies that accompany, reinforce, reorient, and plan public policies aimed at improving care for mothers and children. It was important to scale the “Camino verde de la embarazada” program to the outpatient setting in hospitals while also conducting low and high risk prenatal care. The main obstacle was to obtain absent patients' data to then carry out an active search.

The EHR played a fundamental role in facilitating the necessary data so that pregnant patients can attend the largest number of prenatal care appointments. Nevertheless, there were several challenges including bringing a standard work procedure to health organizations accustomed to working in a heterogeneous and

independent settings. Another challenge was to bridge different levels of care (outpatient offices in hospitals and PHC teams) with various work modalities.

All this entailed carrying out consensus among multiple parties of interest, making it vital to establish general guidelines and organize initial meetings with everyone involved. In this way it was possible to implement this strategy of active search for pregnant patients in nine hospitals, which is not usual in urban areas. At the same time, an automated report on a weekly basis has the advantage of accessing information faster than before, providing the opportunity for a quick intervention.

The projection this proposal contemplates is that each PHC center can access the report of their corresponding population in real time and a new report with the results of the active search in order to carry out an evaluation of the program. In addition, it would be of interest to investigate the lack of adherence to prenatal care of pregnant patients in Buenos Aires City.

5. Conclusion

The implementation of the EHR was a fundamental tool in achieving an active search strategy for pregnant patients in the hospital outpatient setting with the intention of completing the pre and postnatal care recommended by the WHO in order to reduce maternal and child morbi-mortality. This also allowed the opportunity to manage public policy in nearby jurisdictions, as well as pursue more proactive strategies and not have to wait for patients to appear in the health center as the traditional paradigm had previously defined.

Evaluating Quality of Electronic Clinical Notes Using the Spanish Version of Physician Documentation Quality Instrument (PDQI-9) in a High-Complexity Hospital. Cross-Sectional Study

Giuliana COLUSSI^{1a}, Amalia BOTTO^a, Romina GIUDICESSI^b, Laura GOMEL^b, Aldo MARANGONE^b, Miguel RODRIGUEZ^b, Sonia BENITEZ^a

^a *Health Informatics Department, Hospital Italiano de Buenos Aires, Argentina*

^b *Medical Auditing Department, Hospital Italiano de Buenos Aires, Argentina*

Abstract. Introduction: There are factors inherent in Health Information Systems that, when are used improperly, can degrade the quality of the information, which may imply, among other things, the lack of integrity, inconsistency or inaccuracy of the information. **Objective:** The aim of this study is to describe the quality of electronic clinical notes using the PDQI-9 score (Spanish version). **Methods:** We evaluated the judgment on the quality of two medical auditors trained in the use of PDQI-9 tool. The unit of analysis was the 3 types of clinical notes: admission notes, progress notes and discharge summaries of adult patients admitted to general wards. Sampling type: random. Statistical analysis: continuous variables were summarized with median and interquartile range. Medians between 2 reviewers were compared using Mann Whitney hypothesis test. **Results:** 120 Electronic Health Record (EHR) were selected, the median of the overall quality of the admission notes were 33 (31-34) and 32 (32-37) for each reviewer respectively, without any statistically significant differences ($p=0.729$). The overall quality of progress notes and discharge summaries were 28 (27-33) vs 27 (27-32), $p = 0.175$ and 33 (32-34) vs 33 (31-34), $p = 0.243$, respectively. **Conclusions:** The quality of the clinical documents evaluated by the trained reviewers using the PDQI-9 score was good. The application of this type of tool is valuable for making a diagnosis in terms of quality that allows improving clinical documentation, as well as peer communication when reading the Electronic Health Record.

Keywords. Electronic Health Record; Documentation; Clinical Note; Quality; Instrument

1. Introduction

The implementation of the Electronic Health Record (EHR), provides benefits regarding the accessibility, availability, and communication of clinical information,

¹ Corresponding author. giuliana.colussi@hospitalitaliano.org.ar

impacting positively on the quality of patient care [1]. However, there are factors inherent in Health Information Systems that, when are used improperly, can degrade the quality of the information [2], which may imply, among other things, the lack of integrity, inconsistency or inaccuracy of the information [3]. An example of this problem is the inappropriate use of copy and paste, as well as the vast amounts of low-quality information automatically inserted in the clinical notes[2].

In this sense, it is essential to audit the quality of clinical records made by health professionals [4], the main role of medical auditors. In our country, we have a validated tool to evaluate the quality of clinical notes in the electronic medical record, but its use is not standardized. This tool, called Physician Documentation Quality Instrument (PDQI-9), evaluates three clinical notes (admission notes, progress notes and discharge summaries), through 9 items using a Likert scale. Using this tool, a higher score indicates a higher quality of the clinical notes[5][6]. The PDQI-9 was adapted and cross-culturally validated in Buenos Aires Italian Hospital so that it can be used in our healthcare context by Internal Medicine specialists [7]. For expanding the use of this tool the aim of this study was to train clinical audits to use this tool in order to evaluate quality of clinical notes.

2. Methods

A cross sectional study was performed from March to May 2018. The Italian Hospital is a center of high complexity located in the City of Buenos Aires, Argentina. It's a school hospital who covers surgical and medical specializations. The informatic development from each one has been made by its own initiative. Since 1998, the Institution designs and builds its own Health Informatic System [8]. EHRs from non-surgical adult inpatients from general wards were reviewed and admission notes, progress notes and discharge summaries were the units of analysis. They were selected by the following criteria:

Inclusion criteria:

- Adult Patients (18 years or more) hospitalized in non surgical general wards with at least 3 days and no more than 15 days from March to May of 2018.

Exclusion criteria:

- No record of admission notes, progress notes and discharge summaries.
- First or last progress note

PDQI-9 consists of 9 items scored using a 5-point Likert scale (1 -not at all- to 5 -extremely-). Responses are summed to create a total score, with higher scores indicating greater quality. The items included are up-to-date, accurate, thorough, useful, organized, comprehensible, succinct, synthesized, and internally consistent.

In our case, considering that 9 is the minimum value that a document can reach and 45 is the maximum, taking into account that these values are the results of a Likert scale, to confer better interpretability and to be able to obtain results as an opportunity for improvement, the team of researchers chose to interpret the results in 5 categories: 9-17 Poor quality, 18-26 Regular quality, 27-35 Good quality, 36-44 Very good quality and 45 Excellent quality.

Two medical auditors received an one-hour training from the research team, once a week for three months. During the training, clinical notes of inpatients were assessed

and then excluded to participate in the analysis of this work. Auditors evaluated the clinical notes applying the PDQI9 SV tool and shared their views about the quality of them. Every instance was moderated by a member of the research team previously in charge of the tool validation process.

Each reviewer individually assessed every clinical note, the corresponding EHR, and filled a Redcap form to complete the assessment.

For statistical analysis, continuous variables were summarized with median and interquartile range. Medians between 2 reviewers were compared using Mann Whitney hypothesis test. The analysis was performed using STATA 15.

The research project was approved by the institutional review board (CEPI #4092). The study was performed in full agreement with current national and international ethical regulations. The researchers declare no conflicts of interest.

3. Results

120 Electronic Health Record (EHR) were selected and reviewed. The median of the overall quality of the admission notes was 33 (31-34) and 32 (32-37) for each reviewer respectively, without any statistically significant differences ($p=0.729$). The overall quality of progress notes and discharge summaries were 28 (27-33) vs 27 (27-32), $p = 0.175$ and 33 (32-34) vs 33 (31-34), $p = 0.243$, respectively. (Table 1)

Table 1. Variation between reviewers about the Global Quality per clinical note ($n = 240$). HIBA, 2019.

	Reviewer 1	Reviewer 2	<i>p value</i>
Admission notes*	33 (31-34)	32 (32-37)	0,729
Progress notes*	28 (27-33)	27 (27-32)	0,175
Discharge summaries*	33 (32-34)	33 (31-34)	0,243

*Median (IIQ25-75%)

Regarding the quality by the domain (Table 2), most of them were around the value 3. Overall, "Organized" was the domain with the lowest value (admission notes, 3.2; progress notes, 2.9; discharge summaries, 3.2). On the other hand, the best-rated domains were "Synthesized" (admission notes and discharge summaries, 3.8), "Internally consistent" (progress notes, 3.3; discharge summaries, 3.8) and "Up-to-date" (discharge summaries, 3.8).

Table 2. Quality by item per clinical note ($n = 240$). HIBA, 2019.

	Admission notes	Progress notes	Discharge summaries
Up-to-date*	3.7 (0.50)	3.1 (0.80)	3.8 (0.43)
Accurate*	3.3 (0.54)	3.1 (0.70)	3.4 (0.51)
Thorough*	3.6 (0.60)	2.9 (0.67)	3.7 (0.50)
Useful*	3.7 (0.50)	3.1 (0.80)	3.7 (0.50)
Organized*	3.2 (0.50)	2.9 (0.64)	3.2 (0.50)
Comprehensible*	3.6 (0.60)	3.1 (0.72)	3.6 (0.50)
Succinct*	3.3 (0.52)	3.0 (0.71)	3.3 (0.50)
Synthesized*	3.8 (0.50)	3.1 (0.82)	3.8 (0.44)
Internally consistent*	3.7 (0.60)	3.3 (0.81)	3.8 (0.50)

*Media (DS)

4. Discussion

The aim of this study was to train medical auditors to use the PDQI-9 Spanish version in order to evaluate quality of clinical notes. Admission notes, progress notes, and discharge summaries from 120 EHRs were reviewed. Most of the time, the items analyzed were around the value 3. When analyzing domains, admission notes and discharge summaries were better scored than progress notes, especially in organization and completeness. This could be explained by the fact that the first two have text entry in structured fields, while progress notes is recorded in free text format. Comparing with other experiences the quality obtained in this study was satisfactory. In results reported by Hahn [9], the highest-rated note attributes were “comprehensible” (4.7) and “accurate” (4.5) and the lowest-rated attributes were “synthesized” (4.2) and “succinct” (4.2). This difference can be due to the training provided to residents in their education program. In this sense, there is evidence that this score is useful as a measure of performance of training programs to improve the quality of clinical record. As an example, in the study carried out at the Children's Hospital of Wisconsin [10] the impact of a training for residents were measured with the PDQI-9 tool. In addition, Miller et al [11], in 2017 published how from a training program they were able to improve the score of the quality above 40 points after training. The objective of the mentioned studies were not only to measure the quality of the records, but also to use the PDQI-9 results as a quality indicator, because a standard score is useful for tracing training strategies to improve the quality of records. Future studies in our setting are necessary to examine the implementation of education programs centered in improve clinical note's quality.

5. Conclusions

The quality of electronic clinical notes evaluated by trained medical auditors using the PDQI-9 SV tool was appropriate. This adapted tool has the potential to improve the documentation using the record quality level as an indicator.

Evaluation of openEHR Repositories Regarding Standard Compliance

Maximilian FECHNER^{a,1}, Tobias J. BRIX^a, Tobias HARDT, Johannes OEHM^a,
Martin DUGAS^a and Michael STORCK^a

^a*Institute of Medical Informatics, University of Münster, Germany*

Abstract. We evaluated three repositories implementing the emerging healthcare data standard openEHR for their standard compliance, completeness and vendor lock-in. We found the basic functionality to work consistently across all tested repositories. At the same time, no vendor supports the entire API yet. Some functions like template listing differ slightly in their behavior. Some vendors offer additional custom APIs that are easier to use but lead to vendor lock-in. The openEHR standard itself is designed inconsistently regarding data formats and is missing some basic functionality, for example deletion of templates. With openEHR being a young standard, these issues may be resolved in future releases.

Keywords. Health Information Interoperability, openEHR, Software Validation

1. Introduction

Automated exchange of clinical data between hospitals for improved care and research remains an ongoing challenge. Progress in this area is expected to save billions of dollars via reduced redundancy [1] as well as lead to new medical discoveries e.g. through extensive analysis of the resulting big data sets [2].

The Federal Ministry of Education and Research² in Germany set up the Medical Informatics Initiative³ in 2017 to facilitate data exchange between university hospitals. It consists of several consortia, each of which tries to reach interoperability in a different way. The University of Münster is part of the HiGHmed⁴ [3] consortium that decided to use the openEHR⁵ standard to address this challenge.

OpenEHR is a standard for clinical data storage, retrieval and exchange. It separates clinical modelling for clinicians from IT implementation. Interoperability is achieved by creating common data models. Hospitals that use the same data structures can then directly exchange data without the need for further conversion layers. The countries with the broadest deployments of openEHR are Australia, Slovenia and Norway⁶. Countries pursuing a nationwide eHealth strategy and setting standards for interoperability like Norway seem particularly well suited for the openEHR approach [4].

International cooperation is possible via the “Clinical Knowledge Manager”⁷ (CKM) by Ocean Informatics. HiGHmed uses a governance model designed around a local CKM with clear roles and responsibilities [5] that feeds back parts of its work into

⁷ <https://openehr.org/ckm/>

the international CKM. Other countries like Sweden and Australia also use local CKMs [6].

Several vendors implement the openEHR standard and can in theory be used interchangeably, thus avoiding a vendor lock-in. We evaluated three different openEHR repositories for their standard compliance.

2. Methods

Multiple vendors offer patient repositories based on the openEHR standard in varying degrees of completeness. We selected only systems with support for the openEHR query language AQL, since querying records is crucial for our use-case in HiGHmed: Marand's "ThinkEHR" (now "Better Platform")⁸ (version 2.4.6), Ocean's "LinkedEHR"⁹ (version: 0.9 beta) and DIPS's "EHR-Store"¹⁰ (version: 6.1.0.3166). For the sake of simplicity, these will be referred to by their vendor names, i.e. Marand, Ocean and DIPS.

In an openEHR setting, the following terms are being used. An *EHR* is an Electronic Health Record that acts as a container for a single patient. An EHR contains no patient-data directly, only meta information like a UUID. A *composition* contains a single data record of a patient, e.g. the blood pressure or a microbiology report that is then attached to an EHR. A *template* is the structure definition of a composition. It is the equivalent of a schema definition in other languages, e.g. XSD for XML. Templates are substructured with reusable components called *archetypes* that can be queried independently of the template instances they belong to. To save any given data record into an openEHR repository it is necessary to have an existing EHR-container to attach it to, an existing template definition to validate against, and the data itself in the form of a composition.

We used the official openEHR REST API 1.0.1¹¹ to compare the aforementioned solutions regarding completeness, standard compliance and proprietary functions. The openEHR Repository from DIPS was installed on a local machine. Demo installations of the repositories from Marand and Ocean were offered remotely on the vendor's premises. The following methods of the official openEHR REST API 1.0.1 were tested on all three vendors' repositories in both XML and JSON variants:

- Template: Upload, List, Retrieval
- EHR: Creation with custom ID, Creation with assigned ID, Retrieval
- Composition: Upload, Retrieval, Removal
- Queries: Upload, List, Execution

3. Results

The results of the tests of the different API calls are summarized in Table 1. Green values signify standard compliance. Orange values stand for a non-standard compliant solution. Red means that the function is not implemented yet. Grey values mark functions that are not included in the current version of the openEHR standard.

Stored Query List	No	Yes	Custom API

Table 1: Results of the openEHR REST API 1.0.1 evaluation

3.1. Templates

Template upload works across vendors in the standard Operational Template (OPT) format (Ocean accepts only archetype_id version > 0). Retrieval of templates is implemented within Marand using the XML representation and DIPS additionally supports the JSON format. Ocean has not yet implemented the template retrieval functionality. The listing of currently available templates works similarly within Marand and Ocean. The returned list contains the latest valid version for each uploaded template and is only available in the JSON format. In contrast, template listing in DIPS returns all versions of all templates including outdated versions. Therefore, the returned list from DIPS has to be filtered manually for currently valid templates to achieve the same result as in Marand and Ocean. The return values differ, too: Ocean returns only “concept” and “template_id”. Marand returns an additional “archetype_id” and “created_timestamp”. DIPS adds a further “id”, “filename”, “type” and “version”.

3.2. Electronic Health Records

EHR creation with automatically assigned ID in JSON format works consistently across all tested vendors. A possible variant using XML format is not documented in the current version of the openEHR standard. EHR creation with custom IDs only works with Marand’s repository. All three vendors support EHR retrieval in JSON format. Marand and DIPS additionally provide retrieval in XML format.

3.3. Compositions

All tested repositories support the creation and retrieval of compositions in JSON format. Besides, Marand and Ocean support XML retrieval. Composition removal in DIPS is only possible using the custom API, whereas Marand and Ocean provide a standard compliant solution.

3.4. Queries

The results of ad-hoc queries show differences in the naming of columns (#0, #1, #2 in Marand versus path names in DIPS and Ocean), but can be performed on all repositories. Standard-compliant stored queries are only possible with Ocean, but DIPS offers a custom solution. Ocean returns only IDs for EHR-queries via AQL, metadata like systemID and creationTime are not supported. The only supported data format for queries in the tested repositories is JSON.

4. Discussion

We successfully evaluated three different openEHR repositories regarding standard compliance and proprietary functions. The examined repositories show differences in their implementation of the official REST API in every evaluated segment (templates, EHRs, compositions, queries). The most important parts of the official openEHR REST API (template upload, EHR creation, composition creation, basic querying) work consistently across vendors. Thus, repositories can be filled with data and data can be queried with the official API calls. At the same time, every tested repository misses some functionality of the official API. At present, Marand does not support stored queries. Ocean cannot create custom EHRs. DIPS cannot remove compositions. Some functions differ slightly in their behavior, such as template listing in DIPS and AQL EHR queries in Ocean. Since openEHR is a comparatively young standard, these issues may be resolved in future software versions.

Additionally, Marand and DIPS both have extensive custom APIs in parallel to the official openEHR API. These custom APIs are in many ways easier to use than the official version, especially regarding compositions. Both vendors offer a custom “flat” composition format. Adoption of this API means that the “load” part of an ETL-process (Extract-Transform-Load) would have to be redesigned upon a change of the underlying repository. Furthermore, DIPS decided to implement some functions exclusively via custom API, like stored queries and composition removal. This approach is not in line with the general openEHR idea of interoperability and may lead to vendor lock-in.

The standard’s API design itself leaves some areas for improvement, too. At present, there are some inconsistencies regarding data formats. Template upload and download are designed around the XML based OPT (**O**perational **T**emplate) format, while template listing returns JSON. Interestingly, DIPS does not even accept its own template JSON output as a valid input. It remains unclear why this design of alternating data formats was chosen. It might derive from merging of different pre-existing APIs.

Template definition also requires a variety of formats. The XML based OET-format (**O**penEHR **T**emplate) is used for the templates themselves and the custom ADL-format^{12,13} (**A**rchetype **D**efinition **L**anguage) describes archetypes. OETs and ADLs can then be combined into the aforementioned OPT, which can then be uploaded into the repositories. The benefits of the creation of the custom ADL format in addition to the mix of JSON and XML that is already in use remain elusive.

¹² https://specifications.openehr.org/releases/AM/latest/ADL1.4.html#_structure

¹³ <https://specifications.openehr.org/releases/LANG/latest/odin.html>

In summary, working with openEHR requires the use of at least three different data formats (XML, JSON, ADL). Harmonization of the used data formats in future versions of openEHR would be beneficial.

Another point regarding API design is the omission of some basic functions. The deletion of EHRs or templates is currently not supported; therefore, unused records and templates can pile up in the systems and might affect maintainability over time.

5. Conclusion

In their current version, the three tested repositories are standard-compliant regarding the essential parts of the openEHR REST API. None of the tested solutions shows complete support of all official API functions.

Marand and DIPS both have extensive custom APIs in parallel to the official API. These custom APIs are in many ways far easier to use than the official version. Furthermore, DIPS decided to implement some functions exclusively via custom API. These proprietary functions might lead to vendor lock-in. In addition, functions to delete templates or EHRs are missing.

Finally, the official API design itself is inconsistent in its use of data formats. At least three different formats (XML, JSON, ADL) are required to work with openEHR in its current form. Since standards like openEHR are in a continuous improvement process, this might change in future releases.

Formal Modelling of FHIR Based, Medical Data Exchange Using Algebraic Petri Nets

Franziska BATHELT ^{a,1}, Michéle KÜMMEL ^a, Sven HELFER ^a, Christian KAMANN ^a and Martin SEDLMAYR ^a

^a*Institute for Medical Informatics and Biometry, Carl Gustav Carus Faculty of Medicine, Technische Universität Dresden*

Abstract. Enabling interoperability is a challenging task in medical data exchange and is often addressed by the use of versatile communication standards like HL7 FHIR. Although daily routine and scientific experiences show its suitability, the use comes with major risks regarding safety and security of data. To overcome these problems, we present an approach to enable a formal verification of medical communication use cases. We identified the Neonatal Screening as a practical example in which two process participants (physician and screening laboratory) are involved. We analyzed the FHIR specification as well as identified necessary resources in that context and formally modeled them as algebraic specifications. By that, we were able to represent the participants' behavior and data flow with help of Algebraic Petri Nets. This strategy allows to formally verify the correctness of a system by specified requirements regarding data safety and data security.

Keywords. Data Safety, Data Security, FHIR, Algebraic Petri Nets, Neonatal Screening

1. Introduction

Integrated health care depends on both interdisciplinary collaboration of health care providers and communication between their IT systems. Providing the required data interoperability is a crucial task and subject of current research [1].

As an example for a medical process we focus on the screening for Phenylketonuria (PKU), a disorder that is a target of the German Neonatal Screening program [2]. This screening allows the early detection and treatment of congenital metabolic disorders, endocrinopathies and immunodeficiencies in all newborns (given the parents' consent) [3]. For the diagnosis of PKU, a secure and reliable communication between the physician and the screening laboratory is needed. In particular this means, it is necessary to ensure that exchanged data is sent, received and interpreted correctly as well as it is only accessible by authorized participants.

¹Corresponding Author: Email: franziska.bathelt@tu-dresden.de

HL7 FHIR (High Level 7 - Fast Healthcare Interoperability Resources) is a trending important communication standard in health care [4]. It theoretically allows for integrating legal specifications by providing a *Contract Resource* [5], which can include information regarding consent and access restrictions [6].

As these contracts change, IT systems must be manually adjusted. These changes are often tested with the help of simulation methods. However, these methods are usually incomplete, which leads to safety and security problems. This can be countered by formal specifications, which enable the analysis during the concept phase and the possibility to ensure adherence to legal and medical regulations. One possibility to formally specify data exchange processes is to use Algebraic Petri Nets [7] (APNs). APNs simultaneously model control and data flow while being highly comprehensible. It has already been shown that reliable data communication between medical devices can be realized if the devices' internal behavior and data flow are modeled as APNs [8]. We investigate, if it is possible to formally model the participant's behavior and their data exchange for a medical process.

2. Methods

Based on the PKU screening process we proceeded a three step approach.

1. **Modeling of Petri Nets (PN):** The steps of the Neonatal Screening were inferred from the standardized description of the process [3,2] and abstracted for a process model. The participants (physician and screening laboratory) were modeled as Open PN [9].
2. **FHIR Based Data Modeling:** Based on the standardized guideline mentioned above FHIR resources that are necessary for the communication were identified, analyzed and mapped into the structure of algebraic specifications [10].
3. **Modelling of APNs:** The Open PN were enriched with the FHIR-based medical data to model the APNs.

3. Results

3.1. PN Model for Neonatal Screening

The modeling of the Neonatal Screening process, performed by the physician and the screening laboratory, in an Open PN corresponds to the process shown in Figure 4. The physician, who was responsible for the child's birth, has to inform the parents about the Neonatal Screening (p_0, t_0, p_1). The parents can refuse (t_2, p_2) or agree (t_3, p_3). Given consent, the test can be carried out (t_4, p_4). Therefore a sample of blood is transferred to a test card which is sent to the screening laboratory (t_5, p_5). The physician is waiting for the results (p_6). The laboratory physician performs a tandem mass spectrometry (p_{11}, p_{12}, t_{11}) and documents the laboratory experiment at the test card (p_{13}, t_{12}, p_{15}). The result of the examination (p_{14}) can be suspicious (t_{14}, p_{17}) or within normal range (t_{13}, p_{16}). The physician will be informed about every suspicious result immediately by telephone (t_{15}, p_{18}, p_{19}). In both cases, the laboratory physician creates a record of the result (t_{17}, t_{16}, p_{20}) and returns it to the physician responsible ($t_{18}, p_{21}, t_{19}, p_{22}, p_{23}$). When the physician

is informed of the suspicious findings (p_7, t_6), further diagnostic measures are initiated (p_8) to confirm or refute the suspicion. If the findings are inconspicuous, the physician will only be informed in writing (t_{10}, p_{10}) and no further action is required.

3.2. FHIR Based Data for Neonatal Screening

To enable the communication between physicians and the screening laboratory, the following FHIR resources must be considered: (1) The *Patient Resource* includes name and birthdate of the newborn. The Neonatal Screening process also requires communicating the newborns time of birth. As it is not included in the *Patient Resource*, we used the extension *birthTime*. (2) The *ServiceRequest Resource* is needed to inform the laboratory to start the diagnostics. (3) The *DiagnosticReport Resource* includes information about the laboratory results and their interpretation. (4) The *Contract Resource* can include information about access restrictions and consent acceptance.

These resources are connected to further resources; e.g. *DiagnosticReport* might include information about the performer of the diagnostics which can be an organization (*Organization Resource*) or health care provider (*Practitioner Resource*). We abstain from listing all of them in detail for clarity reasons. However, an overview is given in Figure 1.

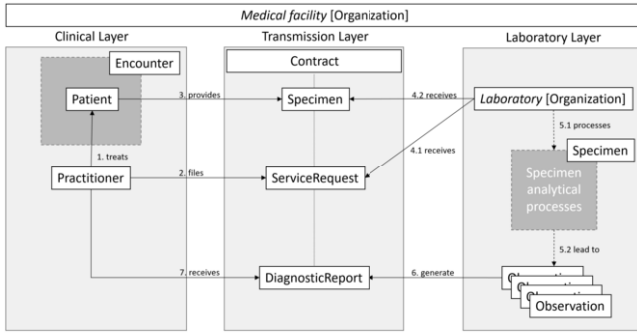

Figure 1. Necessary resources and their connection

By analyzing these FHIR resources, we found a basic structure that can be represented as algebraic specifications, which are shown in Figure 2.

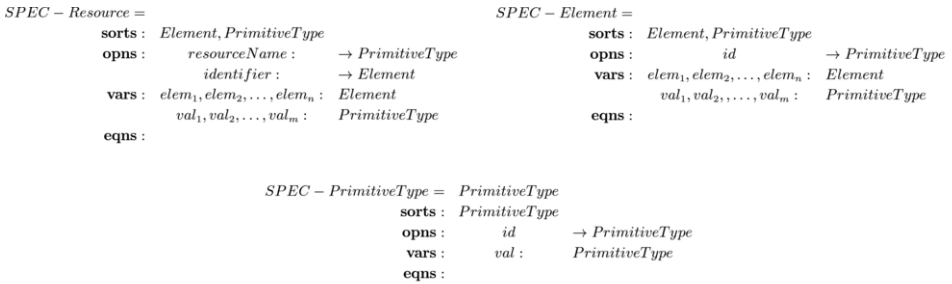

Figure 2. Basic Structure of FHIR resources as algebraic specification

3.3. APN Model for Neonatal Screening

The process of the APN is represented by Figure 4 and the corresponding algebraic specification is described in Figure 3. The algebraic specification is used to formally define data types (e.g. **sorts**: Resource), operations and constants on these data types (e.g. **opns**: $C \rightarrow \text{Resource}$), variables (e.g. **vars**: resourceName: PrimitiveType) and equations (e.g. **eqns**: $\text{resourceName}_C = \text{"Contract"}$). The elements that are defined in the algebraic specification are represented within the PN model, e.g. $\text{arc}(p_1, t_3)$ is labeled with tuple (E, C) , which means that an *Encounter Resource* and a *Contract Resource* are passed.

SPEC – NeonatalScreening =

Figure 3. Algebraic Specification of the Neonatal Screening Process

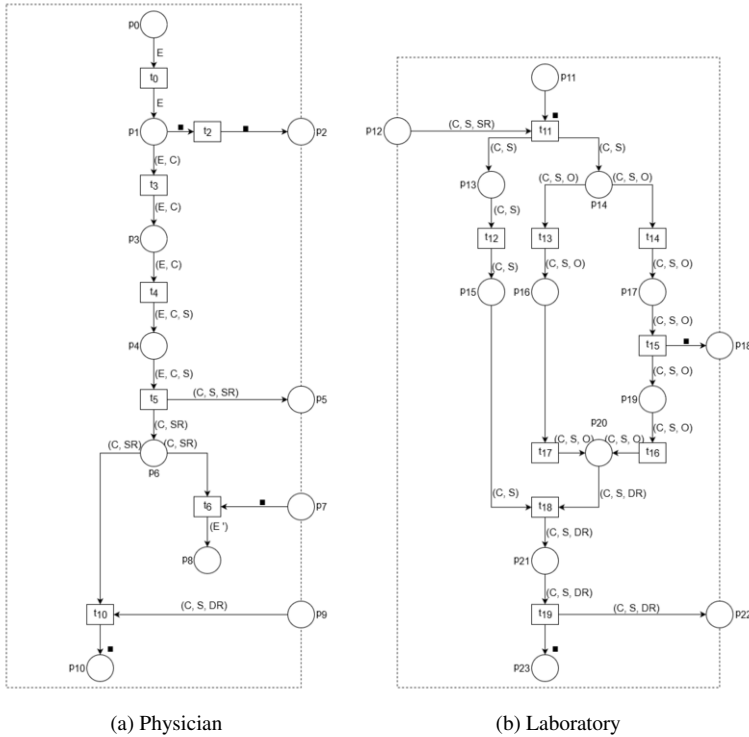

Figure 4. APN for the Physician and Screening Laboratory at the Neonatal Screening

4. Discussion and Conclusion

Based on the Neonatal Screening process for PKU we have shown that a formal modeling of the participants' behavior and their data exchange using APN is possible. By defining a general mapping for FHIR Resources into algebraic specifications a formal data treatment within the concept phase of a system that communicates with FHIR-conform messages becomes possible. The use of the *Contract Resource* enables the inclusion of safety and security requirements into the initial specification. This forms the base to ensure a safe, secure and reliable communication.

The example of PKU screening we described is somewhat limited: It focuses on in-patient births with the test taking place within the first 36-72 hours after birth and we did not include other disorders (e.g. atypical forms of PKU) [3]. Also the modeling process itself leads to an abstraction of single steps. We performed these abstractions in agreement with medical experts.

Albeit these limitations, our approach is a necessary step to formally treat data and its exchange. This will allow formal verification of health care systems. There are currently no approaches but one on data formalization within the composition of communicating systems [8]. To further improve our approach, we aim to include possibilities for representing and verifying time constraints and allow for a real-time adaption process to handle atypical courses of a disease. This could make it possible to test if the prerequisites of a clinical guideline can be met (e.g. process participants, time limits, technology). Also the effects of changes in the guidelines can be theoretically verified and therefore adjustments can be made (e.g. other process participants, changed process steps). These validated guidelines could not only improve the efficiency of health care systems but also patient safety.

Health Metrics Network (HMN-WHO), a Tool to Assess the Quality of the Information System in Burkina Hospitals

Seydou Golo BARRO^{a,c,1}, Amadou DICKO^a, Paul-André DE LAMÉ^b and Pascal STACCINI^c

^aNazi Boni University, Bobo-Dioulasso, Burkina Faso

^bTraining and Research Center of Medical Technology, Bobo-Dioulasso, Burkina Faso

^cRETINES Lab - IRIS department - Medical Faculty of Nice University, France

Abstract An assessment of the quality of the information system was conducted in the 14 hospitals of Burkina Faso in 2017 using the HMN tool (Health Metrics Network). This evaluation was part of the process of developing a master plan for implementing a HIS for the hospitals in the country, and was aimed at analyzing the sub-components of the existing information system. The results are presented as scores, one per component, evaluated in % and converted into quartiles, ranging from the 1st quartile "Not adequate at all" to the 4th quartile "Highly adequate". The scores are as follows: Resources = Q1 (29%); indicator = Q2 (46%); data sources = Q1 (28%); information production = Q1 (21%); data management = Q2 (47%); dissemination and use = Q3 (55%). In conclusion, overall the system is not adequate (mean score 39%), particularly at the level of information production (score 21%).

Keywords: HMN Tool, Information System Quality, Hospitals, Burkina Faso

1. Introduction

In the health sector, it is critical to have high-quality data on performance available routinely [1-3]. Improving the performance of a country's national health information system depends on the quality of its healthcare information system. To address this challenge, the Ministry of Health of Burkina Faso recommended that each Hospital Center develops a Master Plan for implementing their Hospital Information System (MPHIS) [4,5]. It is within this framework that we conducted a study to evaluate the quality of the information system in terms of data collection and management in the fourteen (14) hospitals the country counts. The aim of this study was to analyze the current data collection and management processes to have a baseline evaluation, and then to follow its progression. In order to measure the performance of the system's components and ensure the comparability of the results between countries, the World Health Organization (WHO) and its partners have created an evaluation tool called "HMN" (Health Metrics Network). It has two parts, the normative portion (components and standards) and an implementation portion (a roadmap) [5]. The purpose of this tool is to create a harmonized framework for the development of a national health

¹ Corresponding Author, Email: golo-seydou.barro@univ-amu.fr.

information system that meets specific standards. The HMN methodology provides a comprehensive assessment of the system's environment and organization, the responsibilities, roles and relationships between actors as well as the technical and technological aspects related to data collection and analysis. The organizational, functional and technical components are the elements that we evaluated.

2. Methods

The evaluation focused on the following six sub-components: (i) background and resources: policy, regulatory and financing aspects as well as the available infrastructure and resources; (ii) indicators: basic indicators of disease management and health promotion; (iii) data sources: population census, vital statistics, population surveys, patient records and registers, care units reports; (iv) data management: data collection, sharing, and storage; (v) information production: quality of the data, especially aspects of transparency, disaggregation, representativeness, consistency, periodicity, timeliness, completeness and collection method; (vi) dissemination and use: information dissemination flow, use for decision-making, including policy development, advocacy, planning, implementation of interventions as well as follow-up and evaluation. Regarding data collection of the relevant information, different forms have been designed. The data collection was carried out by groups of people assessing a specific component of the tool in each hospital. The number of assessors varied from 3 to 5 depending on the importance of the component. People in each group were asked to assign a score between 0 and 3 to each item of the component they were assessing and then to compute the average score per item. Collected data were recorded in the electronic version of the tool programmed to provide the results of the evaluation automatically. The results were converted into four groups or "quartiles" defined on an ordinal scale and reflecting the evaluation of the performance of the system by the respondents: group 1, score $\leq 25\%$, "Not adequate at all", corresponds to the first quartile; group 2, between 26% and 50% "Present but not adequate", corresponds to the second quartile; group 3 "Adequate", score between 51% and 75% representing the third quartile; and group 4 "Highly adequate", score between 76% and 100%, corresponding to the fourth quartile. The main difficulties encountered in our study were the unavailability of respondents, access to information and documentary evidence. The results of the evaluations are presented as bar charts and tables.

3. Results

The results of the evaluation showed some achievements, but also many shortcomings. For better consistency, the results of some components have been combined to make it easier to understand.

3.1. Components resources, indicators and data sources

The evaluation showed that both resources (32%) and indicators (46%) were not adequate with a very low score for implemented policies (16%), Table 1.

Overall, the data sources are not adequate (38%), Table 2. The sources that are adequate are those for which activities are systematically performed. These are the inventory of resources (55%). Civil status is the least adequate source (10%).

Table 1: Resources and indicators component

Categories	Max i	Score	%
Policy and Planning	30	4,9	16
HIS institutions, human resources and financing	15	8,8	59
HIS Infrastructure	12	4,4	37
Total	57	18,1	32
Indicators	15	6,9	46

Table 2: data source component scores

Data source	%
Census	32
Vital statistics	10
Population-based surveys	41
Health and disease records	37
Health service records	50
Resource records	55
Total	38

3.2. Dissemination and use of data component

Overall, use and dissemination are adequate (55%), Table 3. This result is mainly attributable to the use of information for action and advocacy (64%) as well as to the use of data analysis tools (61%). Use of information for resource allocation as well as use of information for action is low (44% and 45%). These unsatisfactory results may be explained by the fact that decision makers require complete, timely, accurate, useful and validated information, which is not always the case in hospitals. The integrated HIS analytical reports are produced and cover most of the main health indicators.

Table 3: Presentation of the dissemination and use of information data component

Categories	Maxi	Score	%
Analysis and use of information	12	7,3	61
Information use for policy and advocacy	3	1,9	64
Information use for planning and priority setting	6	3,5	59
Information use for resource allocation	6	2,7	45
Information use for implementation and action	12	5,2	44
TOTAL	39	20,7	55

3.3. Information products component (quality of information)

The mean score of this component is 21%.This score, by the tool standards is considered as "Not adequate". Only "periodicity", "representativeness" and "data-collection methods" criteria fall in the adequate zone. The other criteria are not adequate and are in the second quartile. These are: promptness, completeness, and method of estimating quartile information.

3.4. Evaluation summary

The evaluation summary results presented in Figure 1 shows that the quality of the information system is not adequate. The overall mean score is in the 2nd quartile (39%), so "Not adequate". The best score of the system is related to dissemination and use of information. The worse score is related to information production (21%).

Figure 1. Overall information system indicators scores

4. Discussion

The National Health Information System of Burkina Faso is not efficient, particularly regarding its hospital sub-system. This was the rationale for this evaluation, which allowed to identify its strengths and weaknesses. The strengths of the hospital information system are a good organization of the services, a legislation related to mandatory reportable diseases, tools for collecting information, databases built with DHIS2 [4,5], procedures for implementing the principles of official statistics, effective means for cross consultation at all levels. There are also weaknesses, for example not including some parameters such as civil status. Social insurance is very limited. Moreover, there is no systematic evaluation of the hospital information system contrary to what is done in the peripheral health structures. Indicators of health status (maternal and infant mortality) are not adequate at all (21%). This is partly due to the lack of performance of the civil registration process and the lack of a good certification system of the causes of death [6]. In addition, administrative statistics do not always guarantee the quality of certain indicators such as deliveries attended by qualified personnel. There are indicators discrepancies revealed during the surveys [7]. It should also be noted that the results evidenced the existence of a true coordination problem in the management of information as reported in Botswana in 2015 [8] and in the study by Lippeveld T et al. [9]. There are also problems due to the lack of equipment, financial resources and qualified personnel as reported by Verberk et al in 2004 [10]. Of the 14 hospitals, Bogodogo District Hospital and Tengandogo District Hospital have the highest scores with 62% and 69% respectively. We must mention that these two hospitals are recent institutions that benefitted from the support of certain partners such as the Chinese cooperation. The indicators of data dissemination and use got the highest score in our evaluation (58%). However, these scores remain low by current standards and show an underutilization of information in the hospitals of Burkina [11]. The results of the evaluation show the total score of the components is 39%. A similar score was found in an evaluation carried out at the University Hospital Center of Oran in Algeria (37%) [12].

5. Conclusion

The evaluation of the hospital information system using the HMN tool has identified indicators measuring the performance of the information management system against current standards and practices. The analysis of the existing system made it possible to identify its strengths and weaknesses to extrapolate the needs for the design of the future system. It also evidenced the achievements and efforts that remain to be made in order to have an efficient and effective information system. The evaluation showed the weakness of the activity coordination, the poor quality of certain indicators, the insufficient exploitation of the databases and the low level of data production and dissemination of information. These are all the reasons that justify the development and implementation of a Master Plan for a Hospital Information System (MPHIS). This will have the advantage of unifying the efforts, coordinating the actions and harmonizing the information management at the national level. The implementation of the MPHIS also has the advantage of harmonizing the population numbers (reference population), to strength the quality of the subsystems and to improve dissemination of information. Health data sciences and mobile health (mhealth), will be an important contribution to the management of massive data produced in hospitals [10,11,13].

Abstract. The access to data in healthcare is an enabler for the implementation of clinical decision support systems (CDSS) in practice. The usage of CDSS aims to be of efficient assistance to healthcare providers. The aim of the BMBF project “PosiThera”, is to support the involved professions in the treatment process of chronic wounds. In this study we implemented the formalized knowledge of chronic wound diagnosis into two different knowledge base approaches, the HL7 Arden Syntax and a Petri net approach. The motivating factor behind our study was to use both approaches for the implementation of the projects knowledge base and to compare the results. We implemented the formalized knowledge successfully in both approaches. The results of our comparison showed similarities and differences of the Arden Syntax and the Petri net approach, which might support the evolution of both approaches in the future.

Keywords. Clinical Decision Support, Arden Syntax, Petri net, Chronic Wound

1. Introduction

IT infrastructures have become increasingly important factors in the healthcare system especially for information exchange. The changing paradigm from the paper-based health record to the electronic health record promotes the rising of clinical decision support systems in practice, as the access to data is a crucial requirement for the processing of decision support algorithms. Key components of clinical decision support systems are the knowledge base and the inference engine. Both are required to implement and process knowledge for a CDS System. [1, 2, 3]

The BMBF project “PosiThera aims to develop a CDS System for the diagnosis and treatment of chronic wounds [4]. The research aim of this study was to develop and compare two different implementations of the project’s knowledge base and inference engine by using HL7 Arden Syntax and a Petri net approach.

2. Methods

The development process of our system was based on the knowledge engineering process recommended by Waterman [5] and Durkin [6], which is structured into the steps: (1) Problem assessment, (2) Data and knowledge acquisition, (3) Development of a prototype system, (4) Development of a complete system, (5) Evaluation and revision of the system, (6) Integration and maintenance of the system.

This study gives some results for step 3 for the use case diagnosis of chronic wounds identified in step 1 [7]. The knowledge implemented in the prototype was obtained by analyzing S3 guidelines (3), publications (5), and literature (3) in the context of chronic wound treatment to extract and formalize the knowledge with the focus on our use cases (Step 2). In the formalization process we developed 60 production rules and 3 decision trees.

To implement the formalized knowledge we tested two approaches and compared their performance based on a list of project specific criteria, which are as follows: Binding of Data Ressources, Logical Operators, Medical Logic Organization, Human Interpretable, Knowledge Base Scalability, Maintainability, FHIR Connection, Forward Chaining Algorithm implementable, Backward Chaining Algorithm implementable, and Uncertainty (Fuzzy Logic).

HL7 Arden Syntax was selected, because it is an established and standardized approach to implement machine executable medical knowledge [8, 9]. The Petri net approach was chosen, because it is already implemented in a software product of Atacama Software GmbH in the context of nursing.

2.1. Approach HL7 Arden Syntax

Arden Syntax is a HL7 standard for computerized knowledge representation and processing [8, 9]. It can be used to create knowledge bases for CDS systems and enables the execution of machine-readable medical logic modules (MLM). The main components of every MLM are Maintenance, Library, Knowledge, and Resources.

“Maintenance” contains metadata about the MLM, like version identifier, first implementation, and update. “Library” contains information about the MLM’s context. Crucial for example is in which use case the MLM should be used. This requires knowledge sources and institution specific source linkages used to implement them. The “Knowledge” section represents the processing logic of the MLM, which is expressed as production rules. “Resources” allow to define different language specific messages.

Within this study we concentrate our efforts on the knowledge section.

2.2. Approach Petri net

Within the work of a Bachelor thesis at the University of Bremen in cooperation with the company Atacama Software GmbH [10], an implementation of an extended Petri net and a programming language have been developed, which are now also used within the product apenio by Atacama Software GmbH. The extended Petri net enables defining and processing logical rules modelled after most knowledge bases. Each net is defined by: Places, Arcs (flow relations) and Transitions.

Any place is being mapped with a logical entity of the defined logical structure and can be marked with one or more tokens. A token represents a unique object of a place and can have varying attributes. Arcs are directed flow relations between a transition and

a place. They can contain Boolean expressions, which are executed on the tokens of their place. The place with an arc aiming on a transition is called input, otherwise output place. If the conditions of a transition are fulfilled, then it is called activated. An activated transition can fire. Firing means that tokens of the input places get consumed and a token in the output place will be generated. Based on a starting state of a Petri net with multiple tokens in some places (called marking) there is the possibility, that one or more transitions in the net can be fired and a new marking can be reached as a result. An example for the firing process of the petri net is illustrated in figure 1.

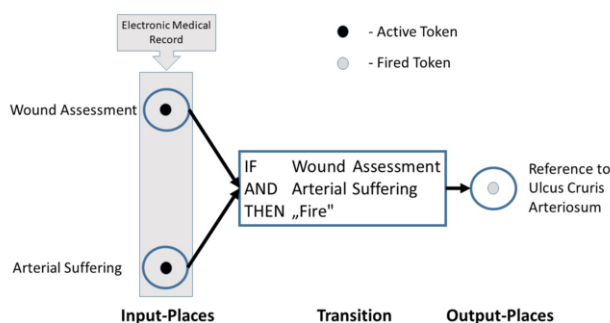

Figure 1. Firing Process of the Petri net approach

3. Results

We were able to implement the knowledge base on the use cases diagnosis and therapy of chronic wounds successfully in both approaches. Based on our criteria list we compared the Petri net approach of Atacma Software GmbH and HL7 Arden Syntax. The results of the comparison are summarized in table 1.

3.1. Similarities

In our study we could identify a variety of similarities between the Petri net and Arden Syntax approach. Medical Logic Modules build up the core to implement medical knowledge in the Arden Syntax. These logic modules are highly standardized (see chapter 2.1). In our use cases it was necessary to organize the modules in file archives which are related by usage context. For example, an archive would consist of causal diseases of an Ulcus Cruris Arteriosum or Ulcus Cruris Venosum. In comparison the Petri net approach is not as highly standardized as the Arden Syntax, but the logic modules can be organized as well in an archive hierarchy. This organization in both approaches enables a sufficient maintainability and scalability. Both approaches use a versioning of Logic Modules to support the developer in cases of maintaining the knowledge base.

The Arden Syntax as well as the Petri net approach operationalize the logic modules by production rule algorithms. These can be implemented as forward and backward chaining procedures, which make both approaches quite flexible to solve complex decision problems.

One benefit of the Arden Syntax is the high performance in human interpretability. The Petri net approach can be supported by easy to read excel lists which contain the medical logic. This approach is different in comparison to the Arden Syntax, but also enables non-informatical professions to understand and discuss about the module contents.

For our implemented use cases both toolboxes of logical operators were sufficiently fitting.

3.2. Differences

While there are a lot of similarities, there are as well differences of the approaches. We could identify, that the binding of data resources is handled differently by both approaches. The Arden Syntax binds data resources separately in every medical logic module by a curly braces statement, which refers to a data source. The Petri net of Atacama Software GmbH uses a central data binding module. The benefit of a central data binding module is to avoid redundancies and could lead to higher transparency in more complex knowledge bases.

Decision scenarios under uncertainty can be solved through the Arden Syntax since version 2.9 by the implementation of fuzzy logic. The Petri net solution does not implement fuzzy logic but can be extended by a Bayes net to deal with decisions under uncertainty.

The usage of the HL7 standard FHIR is implemented in at least one commercial work suite solution of the Arden Syntax as a FHIR connector. The implementation of communication standards in context of scalable data-exchange is beneficial in cases of clinical decision support applications, for example by connecting the CDS System to a hospital information system (which can provide a FHIR interface).

The Petri net approach does not provide a FHIR interface, but a REST interface.

Table 1. Comparison Table of the Approaches Petri Net and Arden Syntax

Criteria	Petri net	Arden-Syntax
Binding of Data Ressources	Central Data Binding Module	Curly Braces in every MLM
Logical Operators	Fitting for the use cases	Fitting for the use cases
Medical Logic Organization	Blocked Production Rules, Archive	Medical Logic Modules, Archive
Human Interpretable	Yes	Yes
Knowledge Scalability	Yes, but increasing conflict management of rules	Yes, but increasing conflict management of rules
Maintainability	Logic Modules Versioning	MLM Versioning
FHIR Connection	Customizable	FHIR Connector in commercial product,
Forward Chaining Algorithm implementable	Yes	Yes
Backward Chaining Algorithm implementable	Yes	Yes
Uncertainty (Fuzzy Logic)	Customizable	Yes

In conclusion, we could identify that the Petri net as well as the Arden Syntax approach are quite similar in their functionality. The main differences we were able to find in the areas FHIR Connection, Binding of Data Resources and Uncertainty.

4. Discussion

In the context of our project PosiThera the study was quite helpful for the future work relating to the evolution of our system with focus on extending the knowledge base. The results show gaps of both approaches as well as benefits and desired functional objectives, which may become relevant for further improvement in the future. Especially the Arden Syntax as established standard could benefit from the results of our study. Suggestions to evolve the Arden Syntax could be to provide a standardized FHIR interface and develop a more fitting solution for the binding of data resources. A second suggestion might also be a good start to overthink and advance the semantic interoperability issue of the Arden Syntax, known as “curly braces problem” [11].

5. Conclusion

In this study we were able to show similarities and differences of the approaches HL7 Arden Syntax and the Petri net approach of Atacama Software GmbH. Both were used to implement our projects use cases. For the ongoing project we decided to use the Petri net approach to benefit from existing interfaces like the connection to a terminology server. What we discern from our study is, that the knowledge modules could be easily transferred from the Petri net approach to the Arden Syntax as well as the opposite direction, which might be of benefit for our future work.

Information Capturing in Pre-Hospital Emergency Medical Settings (EMS)

Kerstin DENECKE^{a,1}, Lea MEIER^a, Jan G. BAUER^a,
Matthias BENDER^a, Christopher LUEG^a

^a Bern University of Applied Sciences, Bern Switzerland

Abstract. Emergency medical situations are characterized by high physical, cognitive and mental demands on the paramedics on the ground. Studies suggest that crucial information such as treatments administered to patients is often documented retrospectively, during patient transport or once a patient is handed over to an emergency department. Information access may also be surprisingly difficult (e.g. patient medical history). In this paper, we focus on supporting in situ information capturing and report on a realistic laboratory-based study involving experienced paramedics that we used to explore the specific requirements and constraints of supporting in situ information capturing. Specifically, we focused on ways to use audio and visual data capture methods and how they need to be designed to better support paramedics without interfering with their work. We then use the resulting information centric perspective to argue for a roadmap towards smart emergency medical services.

Keywords. Emergency medical service, information systems, emergency communication, emergency documentation, EMS, paramedics

1. Introduction

Emergency medical service (EMS) providers play a crucial role in identifying, treating and transporting patients suffering from time-critical emergency medical conditions. In particular when following the Franco-German model of EMS delivery, patients are treated on site which requires complex clinical judgements [1]. In this context, EMS providers perform urgent actions such as the initial assessment of patients in need and treatment as required (vital signs, intravenous fluids, cardiac monitoring, and stabilization). The decision making leading to interventions requires comprehensive medical knowledge of the physiology and pathology of the human body as well as any pharmacological knowledge of drugs to be administered. Appropriate documentation is required, including documenting the patient's initial condition, the care provided by first responders and EMS providers, the status of the patient during the ambulance transport and responses to any treatment [1,2]. A number of studies [3-5] identified a range of problems that are likely to occur over the course of this complex and time-sensitive process and that may impact on the quality and completeness of the information collected. Common mistakes include insufficiently communicated details of the medical intervention on-site [3-5] or an undocumented initial condition of the patient [6].

¹ Corresponding Author: Kerstin Denecke, Bern University of Applied Sciences, Institute for Medical Informatics, Quellgasse 21, Biel, Switzerland; E-mail: kerstin.denecke@bfh.ch.

Elements such as prehospital hypotension, Glasgow Coma Scale score, and other prehospital vital signs [4] or key elements of the history (witnesses, predisposing factors, and post-event symptoms) and physical examination [5] are not recorded consistently. Some of these problems can be attributed to the fact that EMS personnel may have to remember key information in the above-mentioned stressful setting and only gets to document information once a mission is completed or even towards the end of their shifts [7]. To address these issues, digital protocols become increasingly available in EMS, for example the Medical-Pad provided by Tech2Go (<https://www.tech2go.de>). Some of these systems allow for automatic data capturing from medical devices such as ECG. Speech recognition technology [8] and the use of body worn cameras [9] have been explored, but research in this field is still in its infancy.

In this paper, we report on a realistic laboratory-based study involving experienced paramedics that we used to explore the specific requirements and constraints of supporting in situ information capturing. We present our study design and discuss our findings. We also use the resulting information centric perspective to argue for the need for a roadmap towards smart emergency medical services, and conclusions regarding possible concerns to be addressed.

2. Exploring Options for Real-Time Data Capturing during EMS Delivery

The Medical Informatics *Living Lab* at the Bern University of Applied Sciences in Biel, Switzerland brings together expertise in a range of relevant IT (information systems, process design, human centred design), clinical experiences as well as substantial, hands-on EMS experience. We collaborated with local EMS providers to set up a laboratory based study that helps us to probe the suitability of different in situ data capture methods (audio, visual) and how they could be designed in such a way that they fit paramedics' ways of working without interfering too much with their work practices.

2.1. Experimental Setup

The study was designed around medical emergencies using SimMan, an advanced patient model that can be programmed to simulate medical cases of varying complexity. Two conditions requiring interventions were designed, anaphylactic shock (scenario 1) and a low-back injury (scenario 2). Visible injuries and pain zones were marked on the SimMan by images or text. A skilled research assistant was present on site and adapted the vital signs of SimMan during the study as to simulate the patient's responses to treatments administered. A mission was considered to be completed once the "patient" was stabilized and considered ready for transport by the paramedic team. Each of the teams of paramedics had to handle both cases in the same order with a 10 minutes break in between. We implemented the Wizard-of-Oz method [10], a method used for evaluating technology, interaction methods, and technology acceptance without the need to put the actual technology in place. In this particular study, the Wizard-of-Oz method enabled paramedics to document a situation or a particular aspect thereof (e.g. the visual impression of a wound) by using voice commands to "activate" in situ data capturing. The corresponding audio or visual recording was then administered by the research assistant standing in for the actual technology. Once the teams completed each of the two EMS deliveries, paramedics and researchers met to review and discuss the video recordings of the earlier EMS missions. In these reviews, participants were encouraged

to discuss their use of the "live" documentation feature and also whether they would have preferred different types of recordings (different angle, duration, close-up, wide-angle) or even different media (e.g. a voice recording instead of video recording or video recording where a photograph was taken).

2.2. Data Collection

We recruited as participants four experienced, active, male paramedics between 32 and 41 years old (average 36.5 years) from EMS providers based in the Swiss Canton of Bern. Their work experience ranged between 4 and 12 years (average 8.25 years). Following the Franco-German model of EMS delivery they were to form teams of two. Participants were made aware that the experimental setup was realistic in the sense that be provided standard EMS equipment and that fully engaging in the EMS delivery would likely lead to physical exertion and physical stressors. Participants wear body worn GoPro cameras attached at chest level that documented the EMS delivery roughly from their point of view. As explained earlier, participants could also, at any point in time, "activate" documenting by picture/video/audio recording. This feature did not use the body worn cameras but would allow "free form" data capturing as per participants' specifications. Data collected included number of audio/video/photo recordings requested during the course of the live experiment, the number of audio/video/photo recordings requested while watching the footage, reasons for requesting media as recalled by participants, additional data needed (e.g. data transfer from medical devices such as ECG). Data regarding live recordings was then compared to data recording requests as they emerged during the review.

3. Data analysis and interpretation

In terms of duration it took the two teams between 6.85 and 8.50 minutes to have "patients" suffering from anaphylactic shock and a low-back injury stabilized and ready for transport which is in line with what our own EMS experienced personnel who designed the scenarios expected. The following data requests were made during the course of the experiments (see Figure 1): Audio recordings were requested most ($n=13$), followed by taking a picture ($n=8$). Some video recordings were taken during the mission ($n=3$) to document the overall situation. Participants asked only rarely ($n=1$) for transmitting data via external interfaces (e.g. vital parameters from monitoring systems to the documentation record). When reviewing the footage captured during the live events the paramedics would have preferred to use different data capturing methods: In general, more audio recordings were requested ($m=22$) when reviewing the recording than were requested during EMS delivery. Some video recordings were replaced by other media during the review ($m=2$). While watching the recording they asked more for data collection via external interfaces ($m=8$). The scatterplot (see Figure 2) shows that audio recordings were mainly used for documenting the medical history and administered medications during the mission and afterwards. Pictures were largely requested for documenting wounds and for medical documentation (for example, the documentation dossier of the nursing service). The video recordings were exclusively requested for recording the overall situation.

We looked into reasons why there were these differences between Wizard-of-Oz enabled data capturing during the course of the live event and changes to the way

recordings were made during the retrospective review. One reason is that participants realized that audio recordings would not only help them remember certain aspects but that audio recordings could also be used to transfer data directly to an electronic version of the emergency protocol, via speech-to-text processing, therefore replacing the need for manual data entry. Paramedic participants explained that sometimes, it is difficult to verbalize an emergency situation in a way that all parties can understand the overall situation and surroundings. A video recording could help and was requested in the live event. However, during discussions, participants changed their opinion and preferred taking pictures of the overall situation instead of the initially requested video recording. A reason given for this is that pictures might be more meaningful and, more importantly, provide relevant information at a glance without having to watch a video. During the course of the live event, vital values were documented using audio (paramedics reading the values aloud) or photos (taken of medical devices). During the review paramedics would have preferred to have used audio only if this allowed them to have the data directly entered into an electronic version of the emergency protocol, via speech-to-text processing.

Figure 1. Comparison of requests during and after the scenarios

Figure 2. Scatterplot of requests during and after scenario correlated with documentation activities.

4. Discussion and future work

In this paper, we described a study to probe usefulness of different data recording approaches during EMS missions. There is some evidence that incident documentation in EMS could be supported by speech-to-text technology that would allow to enter data directly into the electronic emergency protocol which is needed for documentation purposes and for hand-over to emergency department staff. It is believed that this could help ease the problem of gaps or errors in documentation which are often due to retrospectively collected data. We would expect this to improve both timeliness and correctness of documentation. Ho et al. argue that body worn cameras could help increasing documentation accuracy [9]. While our research supports this observation, we also observed that user acceptance is a critical issue in this context. Participants recognized the benefits of a video recording including increasing their personal security during a mission. However, they were also keenly aware of potential legal ramifications. They know just too well that in emergency situations, decisions regarding treatments may need to be made in a split second and they may include non-standard treatment methods. A potential solution against the fear of after-mission misinterpretations of recordings might be that the recordings are only made available afterwards if paramedics explicitly agree or can add explanations to avoid misunderstandings by not involved

persons. We conclude, there are use cases for video recording in EMS settings, but research is still necessary to find solutions that are accepted by the paramedics and do not hamper the working process.

Given the results of the study, we envision an intelligent rescue environment that supports real-time documentation, direct data capturing from devices, and electronic data transfer to the hospital information system. Further, paramedics have to be equipped with intelligent devices that automatically scan the environment for upcoming risks (like dropping material, changing environment due to weather changes) and provide intelligent decision support as needed, possibly involving services like a telemedicine approach via video guidance [11]. We are currently developing and evaluating a novel system that allows to capture data in a digital EMS protocol using speech recognition technology specifically designed for Swiss EMS and look into its integration with medical devices to enter vital signs into the protocol automatically and to implement data transfer using the CDA-CH RESP standard. In future, we will include methods for ontology mapping (e.g. mapping to a medical ontology [12]) and natural language understanding to make our voice user interface more powerful. Relying upon communication standards and medical ontologies will help in ensuring semantic interoperability. Our research clearly shows the need for acceptance (see also [11]) and that we keep in mind that we don't fall into the trap of designing interfaces that are more suitable for patient, logical, rational humans than for EMS staff who get tired, irritated, or distracted [13].

Integrating Pharmacogenetic Decision Support into a Clinical Information System

Kevin TIPPENHAUER^{a,1}, Marwin PHILIPS^a, Carlo R. LARGIADÈ^b, Murat SARIYAR^a, Thomas BÜRKLE^a

^aBern University of Applied Sciences, ^bBern University Hospital (INSEL)

Abstract. Pharmacogenetic testing can prevent adverse drug events but has rarely found its way into clinical routine. One reason is the lack of tools for smooth and automatable integration of pharmacogenetic knowledge into existing processes. Especially, electronic medical records (EMR) represent a suitable environment for such tools. We developed a modular service-oriented prototype of a pharmacogenetic decision support system within an EMR system of the Bern University Hospital. Here, we present the component architecture of our system and discuss issues required for generalizing our results.

Keywords. Pharmacogenomics, pharmacogenetics, decision support, adverse drug events, HL7 FHIR, expert system

1. Introduction

Pharmacogenetics is the study of genetic effects on the metabolic pathways of drugs. About 95% of individuals carry one or more known genetic variants that are important for drug dosing recommendations [1]. Ignoring genetic variation while prescribing a drug can cause adverse drug reactions (ADR) or insufficient drug effects [2–4]. Approximately 20 genes affecting about 80 agents have been identified as actionable in the clinic [5], and the Clinical Pharmacogenetics Implementation Consortium (CPIC) updates continuously related guidelines with dosing instructions for relevant gene-drug combinations [6]. Nevertheless, the actual implementation of pharmacogenetic testing in clinical patient treatment is progressing slowly.

Relling and Evans summarized some general barriers for pharmacogenetic testing in clinical practice: lack of incentives to prevent adverse events; costs and complexity of computational approaches to identify and prioritize genetic variants that influence prescribing decision; disagreement among professional or guideline generating groups; and a lack of awareness of clinicians concerning pharmacogenetic effects. Further, they concluded that the costs associated with pharmacogenetics are shifting from the laboratory testing to the costs for generating evidence-based decisions from the genetic data [5].

Related to existing implementations, Hinderer et al. reviewed 20 pharmacogenetic decision support systems. Sixteen had prototype status and are often built for one

¹ Corresponding Author, Institute for Medical Informatics I4MI, Bern University of Applied Sciences, Quellgasse 21, 2500 Biel, Switzerland; E-mail: kevin.tippenhauer@bfh.ch.

institution. Only one of the productive systems (TreatGx) was integrated with the local EMR [7]. The same lack of EMR-integration is corroborated by the Ubiquitous Pharmacogenomics project (U-PGx), where only one out of the seven involved European countries implemented an active clinical decision support for pharmacogenetics [8]. Having not found any suitable and EMR-related solution, we developed a prototype implementation for assessing gene-drug-combinations in clinical oncology at the Department of Clinical Chemistry of the Bern University Hospital Switzerland (INSEL). Our goal was to derive a component-based approach to support the integration of pharmacogenetic clinical decision support into a broader range of clinical information systems (CIS).

2. Methods

Initially, we identified the main components required for our prototype: inference engine, knowledge base, and data dictionary (see also [9]). Next, we iteratively defined the architecture according to a typical workflow of pharmacogenetic analysis as described by clinicians at the INSEL. We chose the open source tool PharmCAT as the inference engine [10]. It generates pharmacogenetic reports in JSON and HTML from genetic data in the Variant Call Format (VCF) and comes with a set of CPIC guidelines (the clinical knowledge base) in a proprietary JSON format, which we adapted to our needs. To map information about described drugs we used the Swiss medication catalog “hospIndex” [11] which is incorporated in the INSEL EMR system. The link to the EMR user interface was implemented using the HAPI API, an open-source object-oriented HL7 2.x parser for Java [12]. The CDSS user interfaces were created with the proprietary parametrization language of the CIS within the medication module of the INSEL EMR system. In order to verify our prototype, a synthetic data generator for producing VCF data was implemented using the proprietary parametrization language of the INSEL EMR system.

3. Results

The underlying generic system architecture of our solution (Figure 1) considers two different workflows. The first workflow is triggered by the entry of new patient related genetic data and generates a report comprising the relevant pharmacogenetic findings (PGx Report Generator in Figure 1). It uses following components:

- The genetic data repository to store the raw genetic data.
- The knowledgebase with rules to annotate the genetic data.
- The data dictionary to encode the resulting report.
- The genetic annotation engine to generate the pharmacogenetic report.
- The pharmacogenetic report repository to store the report.

When a new genetic record is added to the Genetic Data Repository, the record is pushed to the Genetic Annotation Engine. This engine is supplied with the relevant pharmacogenetic rules from the knowledgebase and with the code mapping (e.g. translating phenotype “Poor Metabolizer” into a LOINC code) from the data dictionary (Knowledge Resources in Figure 1). Finally, the annotated report is added to the shared PGx report repository.

Once a PGx patient report is available (PGx Decision Support System in Figure 1), the second workflow can be triggered by a drug prescription event, which returns the case specific information from the corresponding CPIC guideline. It comprises the following components:

- The CIS, which sends the prescription and receives the decision support result.
- The pharmacogenetic report repository to read the patients report.
- The knowledgebase containing the decision support rules to evaluate the report for the given drugs.
- The data dictionary to encode the results.
- The CDSS-Engine to deduce the correct decision support message.

Upon a new drug prescription, the CIS sends a prescription event with the encoded prescription data to the CDSS-Engine. The CDSS-Engine looks up the encoded drug in the Data Dictionary and loads the corresponding guideline rules from the knowledgebase. If guideline rules are found, the CDSS-Engine tries to find an existing pharmacogenetic report of the patient. If none exists, a warning is sent to the CIS, since a potential pharmacogenetic adverse event cannot be excluded, and a genetic examination might be advisable. If a pharmacogenetic report of the patient exists, the CDSS-Engine applies the guideline rules on the report and returns applicable dosing instructions to the CIS. Finally, the CIS displays the received message to the prescribing physician.

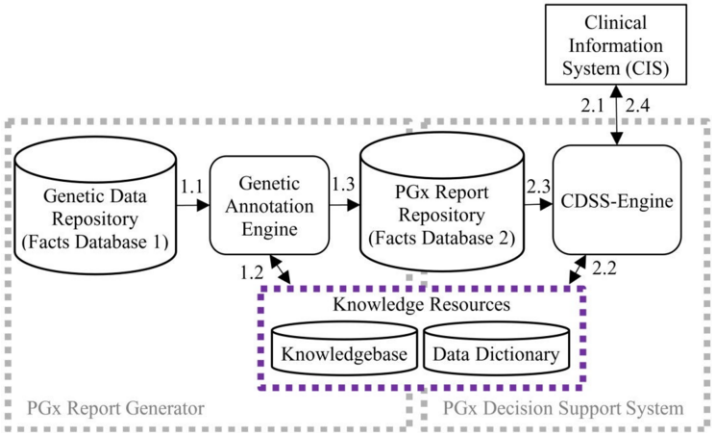

Figure 1. Generic model of a pharmacogenetic decision support system. A Genetic Data Repository acts as the fact database for the Genetic Annotation Engine and provides access (1.1) to the genetic data of the patients. The Genetic Annotation Engine creates a report with the relevant pharmacogenomic findings using the parameters from the shared Knowledge Resources (1.2). The report is stored (1.3) in a PGx Report Repository, which acts as the fact database for a second inference module (CDSS-Engine). Once the rules from the Knowledge Resources have been applied to the patients PGx report, the engine uses the drug prescription from the CIS (2.1) and returns a warning (2.4).

In our implementation, the PGx Report Generator uses a system folder with VCF files for the Genetic Data Repository. A modified version of PharmCAT acts as the Genetic Annotation Engine. The modifications enable PharmCAT to:

- Accept HL7v2 observation request messages as a trigger to read data from the Genetic Data Repository.
- Read the Data Dictionary in form of a configuration file containing the mapping between the genotypes/phenotypes/substances and their encoding.
- Encode genotypes, phenotypes and substances with codes from the Dictionary.

- Turn the pharmacogenetic report into a HL7v2 observation result.

The drug selection event in the CIS oncology drug prescription form triggers the PGx Decision Support System. The CDSS and the PGx Report Repository have been implemented directly within the CIS. The reports from the PGx Report Generator are stored in the database of the CIS acting as the PGx Report Repository for the CDSS-Engine. We implemented the knowledgebase and the data dictionary as internal CIS tables.

For generating synthetic data, we developed a Laboratory Data Simulator (Figure 2). It generates custom VCF data with user defined genetic variants and allows to validate our solution. The following validation workflow was realized in order to compare the issued message with the expected one:

- The validator selects variants to be tested within the laboratory data simulator. The selected variants are added to an existing VCF file template.
- The VCF file is added to the Genetic Data Repository and a HL7v2 observation request message triggers the PGx Report Generator to generate a report.
- The resulting report is returned as HL7v2 observation result to the Pharmacogenetic Report Repository of the CIS and the PGx CDSS is triggered.

Figure 2. Our prototype integrated with the Laboratory Data Simulator (LDS). In the Clinical Information System (CIS), the user can invoke the LDS and generate a genetic data set for one of the test patients. When finished, the LDS triggers the PGx Report Generator with a HL7v2 ORM message (1). The PGx Report Generator reads the genetic data of the patient and creates a PGx report in the HL7 ORU format, which is then sent to the CIS (2). The user can now either switch to the medication prescription user interface and test the actual workflow integration or test the PGx Decision Support System output directly in the LDS. The system supports pre-test and post-test alerts.

4. Discussion

We presented a component-based architecture for genetic decision support during medication prescription. We could identify six generic components, namely a Genetic Data Repository, a Genetic Annotation Engine, a PGx Report Repository, a CDSS-Engine, a Knowledgebase for PGx rules and a Data Dictionary (see Figure 1).

Due to the following reasons, we consider an architecture with two different workflows (writing genetic reports and providing decision support) as mandatory: First, discussions with physicians revealed that access to the pharmacogenetic report is required to assess the content of the CDSS warnings. Second, the processing of large genetic data records would lead to increased response times without a report in which the drug related phenotypes are available. This makes our approach suitable for such large genetic data contexts.

The modularity of the system enables, a hospital to select components from the system architecture according to its requirements and plugging them together. Our prototype implementation does not completely match the proposed architecture. While the PGx Report Generator is indeed loosely coupled with the CIS using the HL7v2

standard, the PGx CDSS itself depends not only on the CIS in use, but also on its configuration within the hospital. In addition, we have not implemented shared knowledge resources. Instead, the PGx report generator and the PGx decision support system have each their own copy of the knowledge resources, which need to be updated simultaneously to ensure the correctness of the results. Such a solution is vulnerable to inconsistencies. To avoid this risk, the knowledge resources should be shared as depicted in Figure 1.

Using proprietary data formats, as we did to access the knowledge resources reduces the systems adoptability. However, the goal should be to provide a plug and play experience for the whole pharmacogenetic decision support system, as proposed, e.g. by the SMART Health IT movement [13]. Hence, a standardized data exchange model such as HL7 FHIR with the modules “Terminology” and “Clinical Reasoning” should be used for interfacing with the knowledge resources.

Abstract. *Background:* C3-Cloud is an integrated care ICT infrastructure offering seamless patient-centered approach to managing multimorbidity, deployed in three European pilot sites. *Challenge:* The digital delivery of best practice guidelines unified for multimorbidity, customized to local practice, offering the capability to improve patient personalization and benefit. *Method:* C3-Cloud has adopted a co-production approach to developing unified multimorbidity guidelines, by collating and reconciling best practice guidelines for each condition. Clinical and technical teams at pilot sites and the C3-Cloud consortium worked in tandem to create the specification and technical implementation. *Results:* C3-Cloud offers CDSS for diabetes, renal failure, depression and congenital heart failure, with over 300 rules

¹ Corresponding Author, George Despotou, Institute of Digital Healthcare, WMG, University of Warwick, Coventry CV4 7AL, United Kingdom; E-mail: G.Despotou@warwick.ac.uk

and checks that deliver four best practice guidelines in parallel, customized for each pilot site. *Conclusions:* The process provided a traceable, maintainable and audited digitally delivered collated and reconciled guidelines.

Keywords. multimorbidity, integrated care, clinical interpretable guidelines, co-production, clinical decision support

1. Introduction

There is an increasing need to organize care around the patient and not on conditions [1], taking into account his or her multiple physical and psychosocial conditions [2]. An integrated, patient-centered care and cure delivery architecture needs to be developed considering the realities of multi-morbidity and poly-pharmacy. This needs to take into account the medical, technological, organizational and socio-economic challenges of creating a collaboration environment for all of the stakeholders involved in the holistic continuum of care. Clinical guidelines re-factor the best available published evidence on clinical effectiveness, into decision trees and care pathways. They are increasingly multi-professional, and work across care providers. However, they usually focus on treating a single disease. Clinical guidelines may clash (e.g., due to incompatible treatment and monitoring regimes). Following more than one clinical guideline, can result in inefficiencies for the patient and for the health system, due to duplicating and inconveniently scheduled investigations and clinic visits, and more importantly, treatments that may exacerbate another condition [3].

C3-Cloud is ICT infrastructure enabling a collaborative care and cure cloud for continuous coordination of patient-centered care activities; by a Multidisciplinary care Team (MDT), and patients/informal caregivers. It implements integrated care pathways for chronic heart failure, renal failure, depression and diabetes, based on best practice guidelines [4]. The C3-Cloud approach to integrated care is demonstrated in varying clinical, technological and organizational settings by piloting in three European regions (South Warwickshire, Basque Country, and Region Jämtland Härjedalen) with considerably different health and social care systems, and ICT landscapes. The paper presents the co-production, and implementation approach adopted in C3-Cloud, which delivers an infrastructure able to offer multiple personalize-able best practice guidelines for multimorbidity. C3-Cloud also incorporates localization, necessary to be deployed in the heterogeneous pilot site environments.

2. The Collaborative Care and Cure (C3-Cloud) Solution to Multimorbidity

C3-Cloud achieves its objectives using the concept of the personalized care plan. The care plan consolidates and reconciles data, goals, treatment, and medications, personalized for each patient, addressing their collective multimorbidity needs, and encapsulating clinical practice guidelines. The care plan can be thought of as an integrated care visualization and management tool. Figure 1 presents the high-level architecture of C3-Cloud and its constituent components, which offer the care plan. The Coordinated Care & Cure Delivery Platform (C3DP) is an innovative online means for multidisciplinary care team members (MDT) to collaboratively manage (execute, monitor, update) the integrated personalized care plans for patients with multi-morbid

conditions. Clinical Decision Support Services (CDSS) support personalized care plan development and execution by clinical guideline reconciliation, risk stratification, poly-pharmacy management, and goal setting and monitoring. A Patient Empowerment Platform (PEP) ensures active participation of patients and their informal caregivers to the management of their multi-morbid chronic conditions, thus alleviating the non-adherence problem. Interoperability middleware addresses technical (TIS), semantic (SIS), and privacy/security (SPS) interoperability challenges to seamlessly integrate with the existing health care, social care, and home/community care information systems. This will allow interfacing the information exchanges, but also the clinical terminology systems between the local systems and C3-Cloud.

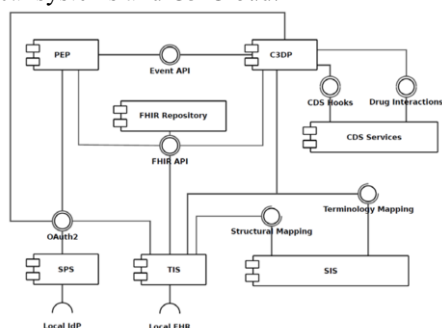

Figure 1: Overview of the C3-Cloud Architectural Components

Finally, all data are stored in a database as HL7 Fast Healthcare Interoperability Resources (FHIR) (<https://www.hl7.org/fhir/>), annotated with the codes of the terminology systems, C3-Cloud uses. FHIR, along with other standards used internally in C3-Cloud, result in an easily maintainable and upgradeable architecture.

3. From Medical Knowledge to Localization and Personalization

One of the main objectives of C3-Cloud is to deliver integrated care, based on best practice guidelines. In order to achieve this, C3-Cloud had to overcome a number of challenges: a) unify and reconcile guidelines to offer the patient a single multimorbidity management plan rather than a digitization of multiple separate guidelines; b) deliver an infrastructure suitable to customize the vision of an enhanced service for all pilot sites; and c) increase patient benefit by offering further personalization options based on what the clinical team of each pilot site identified as important. Figure 2 illustrates a process that enabled co-production of the consolidated and reconciled multimorbidity guidelines delivered by C3-Cloud. Local practice for each pilot site was identified by the clinical teams of each pilot site. Then, pilot sites recorded their vision of an enhanced service, and performed a gap analysis with the current service to identify core functional requirements for C3-Cloud. This includes personalization rules that need to be applied in multimorbidity, which are then translated into service processes. For example, online messaging to adjust goals of a patient, and online patient reported outcomes triggering automated clinical recommendations.

Figure 2: C3-Cloud Consolidated Multimorbidity Guidelines Process

An organizational analysis was then performed to identify how the newly defined capability would be integrated to each pilot site, including allocation of roles, and specification of local procedures. Figure 3 illustrates a comparison of how the C3-Cloud enabled service would fare against existing practice, as evaluated by clinical teams in each pilot site. The evaluation dimensions were identified by the C3-Cloud consortium based on current literature on integrated care. This process was informed by the UK National Institute of Care Excellence (NICE) evidence-based guidelines, which provided a skeleton gold standard that all pilot sites used as reference. NICE guidelines balance best available evidence with cost benefit, ultimately resulting in a gold standard for care. Nevertheless, even the NICE guidelines, offer limited supported to multimorbidity.

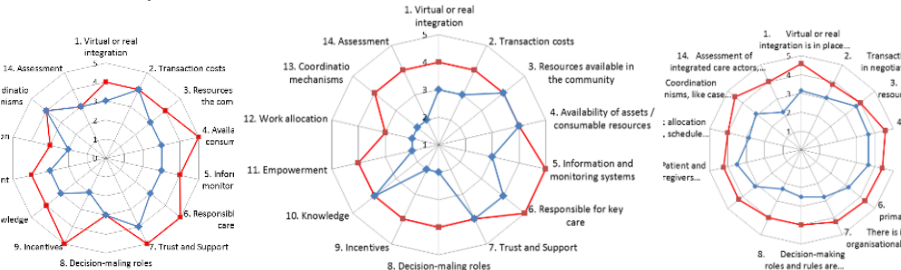

Figure 3: Before and after pilot site internal clinical evaluation of the service

Multimorbidity options, rules and actions, were developed by the C3-Cloud Clinical Reference Group (CRG), consisting of clinicians from each pilot site. The CRG also had overall oversight of the resultant clinical practice. Throughout this process, functional and technical requirements for C3-Cloud were also identified by using a Model-Driven Engineering approach, which resulted in the specification of the software architecture, as well as the system specification document.

4. Implementation of Guidelines in C3-Cloud

The specification of the C3-Cloud guidelines was followed by their implementation, and deployment as part of the system. The guidelines development process resulted in a number of technical requirements for C3-Cloud. They provided requirements such as: data that needed to be stored in the FHIR database; the user interface that users (MDTs and patients) would experience, capturing all aspects of multimorbidity management identified in the guidelines; and automated rules implemented by the clinical decision

support modules. Figure 4 presents the steps followed for implementation of the CDSS logic, and integration with the local sites.

Figure 4: Guidelines Implementation and Deployment in C3-Cloud

In order to meet the interoperability requirements, each step of the C3-Cloud guidelines was annotated with terminologies by the CRG. This allows for unambiguous retrieval of the relevant information from the FHIR repository, as well as an automated interface, which mapped the C3-Cloud terms to the terms used in each pilot site. Furthermore, the guidelines were annotated with the FHIR resources with which they needed to interact. For example, when patients enter data, the system will create an [Observation] FHIR resource, and when the CDSS identifies suitable conditions for certain medications (e.g. beta blockers for high blood pressure), the system will propose to a physician new medication, by creating a [MedicationRequest] resource that they will need to review before approving. This resulted in an annotated logic of the guidelines, that was then implemented using the GDL2 openEMR standard [5]. The GDL2 implementation is deployed as an executable CDSS module, in each pilot site.

5. Conclusions

C3-Cloud had deployed collated and reconciled guidelines on multimorbidity in three European pilot sites. Achieving this required a co-production process involving the pilot site clinical teams, the C3-Cloud clinical reference group, the pilot site technical teams, and the C3-Cloud technical team. The process resulted in over 60 clinical scenarios, 300 CDS rules and over 380 design requirements.

Making a Subjective Notion Computer-Interpretable: The Case of the Tumour-Volume to Breast-Volume Ratio for the Surgical Decision of Breast Cancer

Claudia BLANCAFORT^{a,1}, Jacques BOUAUD^{b,a}, Coralie PREBET^c, Brigitte SEROUSSI^{a,c}

^a Sorbonne Université, Université Paris 13, Sorbonne Paris Cité, INSERM, UMR S_1142, LIMICS, Paris, France

Abstract. Clinical practice guidelines (CPGs) often include ambiguous criteria making their translation as computer-interpretable guidelines a difficult task. In breast cancer management, whether to perform a breast conservative surgery (BCS) or not is one example. Most international CPGs recommend to perform a BCS when the tumour volume / breast volume ratio allows for good cosmetic results, which cannot be directly translated into a computable format. We propose to compute an estimate of the ratio using the maximum size of the tumour to compute the tumour volume and the bra size to compute the breast volume. In addition, we take into account the location of the tumour according to quadrants and unions of quadrants. The model has been tested on a retrospective sample of 34 clinical decisions of a breast cancer unit in a Parisian university hospital (France). Concordance was found in 91.2% of the cases, with good sensibility and specificity. This finding could set a new pathway to advance on the development of actionable decision criteria to be used in a future clinical decision support system for breast cancer management.

Keywords. Clinical decision support systems, Breast cancer surgery, Tumour burden, Clinical practice guidelines, Computer interpretable guidelines

1. Introduction

Although breast cancer happens to be one of the most advanced research fields in oncology, each step achieved implies an increase on management complexity. Professional organisations and expert groups regularly publish clinical practice guidelines (CPGs) in an effort to bring state-of-the-art knowledge to the medical community. Despite literature clearly reports that CPG compliance leads to a significant improvement in overall survival and disease-free survival [1], adherence to CPG recommendations is lower than expected [2]. The development of

¹ Corresponding Author : E-mail : cblancafortgc@gmail.com

multidisciplinary breast cancer units (BCUs) has proven to improve guideline compliance [3,4], but daily practice is hampered by the increasing number of complex patients and data available.

Clinical decision support systems (CDSSs) have been suggested as possible tools to promote the implementation of guideline recommendations. In fact, embedding CPGs in those systems has shown some improvement on overall guideline compliance [5]. In the breast cancer domain, several CDSSs have been developed such as MATE [6], OncoCure [7], OncoDoc [8], or DESIREE [9], but their development remains a challenge. Most CPGs are developed as narrative documents which makes them difficult to be translated into a computer-interpretable format. Clear examples, among others, is the presence of subjective notions, very difficult to be formally modelled, and the reference to decisional criteria which are not routinely collected.

In breast cancer management, the indication of conservative surgery (BCS) against radical surgery is one of the concepts harder to translate. Normally, the goal of surgery is to ensure both local control and breast preservation with an optimal cosmetic outcome. The current standard of care is BCS followed by adjuvant treatment which is equivalent, in terms of overall survival, to a mastectomy. CPGs propose several criteria contraindicating BCS, some of them being objective such as inflammatory breast cancer, contraindications to radiotherapy, or the patient's choice. Apart from these well-defined situations, CPGs recommend to perform BCS if "optimal surgery is feasible, maintaining good cosmetic results". Then, for most cases the decision whether to perform a BCS is subjective, making it difficult to formalize this criterion in order to use it in a CDSS. The Erasmus MC Cancer Institute research group published a series of works dealing extensively with this issue. After determining the three independent predictors of superior cosmetic result after BCS, tumour volume (TV), breast volume (BV), and tumour location, they published a prediction model based on the TV/BV ratio [10,11]. Unfortunately, the direct application of this model remains complicated since neither TV nor TB is part of the routine workup for breast cancer.

In this paper, we propose an adaptation of this prediction model to make it more easily usable, especially for automated CDSSs. Considering that the tumour location is available in patient records, the aim is to compute the TV/BV ratio from an assessment of both tumour size and patient bra size and to translate the notion automating the recommendation of either BCS or mastectomy. In order to evaluate if this approach is concordant with current clinical practice, the model has been tested on a retrospective sample of cases.

2. Material and methods

2.1. Tumour volume

Measurement of a breast tumour volume normally implies complex techniques such as MRI or 3D ultrasounds. These costly techniques are not systematically used in an ordinary breast cancer extension workup. We considered to estimate the tumour volume assuming the tumour to be a sphere. Since the maximum tumour size is essential information in any breast cancer record, we used it as the diameter of the sphere, thus overestimating the tumour volume.

2.2. Breast volume

Even though breast volume can be assessed by MRI and some complex formulas from mammography measurements, still it is not a standard practice yet. Thus, we proposed to extrapolate the breast volume from the bra size of the patient. Bra size is not systematically described in the medical records, but is it is quite commonly used to describe breast size in BCUs. The relation between bra size and breast volume in cm3 was obtained from a technical pattern and sewing association [12], which is used as a manufacturer design standard in France/Spain/Belgium and is reported in Table 1.

Table 1. Approximate bra size-volume equivalents

Volume (cm³)	Contour and cup					
200-250	80A					
250-300	80B	85A				
350-400	80C	85B	90A			
450-500	80D	85C	90B	95A		
550-600	80E	85D	90C	95B	100A	
650-700		85E	90D	95C	100B	105A
750-800			90E	95D	100C	105B
850-900				95E	100D	105C
950-1000					100E	105D
1050-1100						105E

2.3. Cutting points and tumour location

According to the Lagendijk et al. model [11], cutting points below which BCS is expected to achieve a satisfactory cosmetic result are when the TV/BV ratio are below 21.6 in case the tumour is located in the upper lateral quadrant, 4.1 in the lower lateral quadrant, 15.1 in the upper medial quadrant, 3.2 the in lower medial quadrant, and 15.7 in the central position.

Again, a limitation was encountered, since in a substantial number of cases, the location of the tumour is described in the union of quadrants. Thus, we extended the model and assumed that the cutting points in those junctions of quadrants could be estimated by the arithmetic mean value of the cutting points of adjacent quadrants, resulting as it follows: 18.35 for the upper quadrants junction, 3.65 for the lower quadrants junction, 12.85 for the lateral quadrants junction, and 9.15 for the medial quadrants junction.

2.4. Assessment of the method

We performed a retrospective analysis to assess the method on a sample of clinical cases. The study population consisted of female breast cancer patients submitted to BCU meetings between August 2019 and October 2019 at Hôpital Tenon, a university hospital part of Assistance Publique–Hôpitaux de Paris (AP-HP), in France. All patients had given their informed consent to the re-use of their pseudonymised data for research purpose at hospital admission. Cases where collected in October 2019 when the following inclusion criteria were met: (1) Pre-malign or malign breast tumour confirmed by histological evaluation, (2) Radiologic extension study available, (3) Bra

size specified, (4) Decision regarding surgical management made. Patients were excluded in case of bilateral disease, separated bifocal tumours, prior neoadjuvant therapy, or surgical treatment affected by patient's preferences.

3. Results

Among nine BCU meetings, 174 clinical cases were analysed. From 34 to 93 year-old, the average age was 55.9. Both unifocal and close bifocal tumours were taken into account with an average size of the whole tumour mass of 12.8 mm. Eighty-seven medical records specified the bra size (missing data in 50% of the cases). When the bra size was available, the mean breast volume was 556 cm³, which corresponds to a majority of 90C and 95B. After careful review, 34 cases met the inclusion criteria. BCU physicians chose mastectomy (radical surgery) in 26.5% of the cases, whereas the 73.5% of cases left where oriented towards a lumpectomy (BCS).

For each case, TV/BV ratio was calculated and, according to the tumour location, was classified to determine the surgical procedure recommended by our extended version of the Lagendijk et al. model. Then, each recommendation was confronted with the actual decision made by BCU physicians. Concordance reached 91.2%. Model sensibility and specificity were 88% and 100%, respectively; positive and negative predictive values were 100% and 75% respectively.

4. Discussion

Breast volume is not routinely computed pre-operatively because as yet there is no accepted technique to assess its value. Bra size represents an accessible information since most women know it or it can be assessed by simple anatomic measurements. However, there is not much published in medical literature about the relation between breast volume and bra size. On the other side, this relation has been studied in other domains such as sewing and patronage or even plastic surgery prothesis manufacturers. We have found interesting to exploit those sources of knowledge in profit of science.

According to our results, bra-size is recorded by clinicians in 50% of the cases discussed during BCU meetings. Whether this size is obtained by clinical history or by anatomic measurements could not be assessed. Of course, bra size does not characterize breast shape or ptosis, and it has been suggested that more than half of woman population could be wearing a wrong size of bra [13]. Nevertheless, our results showed that it can be feasible to estimate the breast volume to be used in the computation of the TV/BV ratio. Our recommendation is to get the bra size during physical examination, measuring chest and bust. Regarding the tumour volume, assuming the tumour shape as a sphere has no evidence-based studies to rely on, but this approximation has been done by other research groups [14]. In any case, the documentation of the maximal tumour size along with the tumour localisation is mandatory for staging breast cancer.

Given the good results for sensibility and specificity, our extended version of Lagendijk et al. predictive model appears to be secure and could be used in CDSSs as an orientation tool to decide between BCS or radical treatment. The 8.8% non-concordant decisions were cases for which the model suggested mastectomy whereas BCS was decided. These decisions concerned low malignancy tumours, which could explain the choice of BCU physicians for a less aggressive treatment. Accuracy of the

volume measurements (TV and BV) were not addressed in this study. The goal was not to develop a new clinical predictive model, which would require a much more developed methodological strategy and a higher number of cases. Hopefully this issue is already being addressed by important and experienced research groups.

The actual lack of more explicit definitions regarding the surgical choice for breast cancer patients makes it mandatory to invent creative solutions. We believe this finding could alleviate the frustration in creating a more precise computer-based CDSS to assist with the management of breast cancer from evidence-based guidelines.

More Information Continuity Through Health Networks? Barriers to Implementation and Use of Health IT

Özlem TECKERT^{a,1}

^a Faculty of Management, Culture and Technology, Osnabrück University AS, Germany

Abstract. Wound networks, as a voluntary structure formed by interdisciplinary health professionals, have the capacity to improve the continuity of care. Health IT systems (HIT) might be able to support these networks ensuring the information continuity in this process but electronic networking usually fails. The aim of this qualitative study is to examine the barriers why the networks do not take this step and possible approaches on how to overcome them. Based on interviews with 11 managers of wound networks 13 barriers could be detected which can be assigned to the main categories personal, financial, technical and legal barriers. It becomes clear that networks as voluntary bottom-up movements cannot increase the information continuity and hence also not the continuity of care on their own. This requires an overall concept. However, according to health experts, this must be drawn up, financed and above all coordinated by policy makers. In addition, these experts postulate structural guidelines for a cooperation in networks as well as nationally binding processes and standards in wound care. These guidelines and processes should then be mapped in a mandatory central HIT.

Keywords. Continuity of care, health information technology, integrated care, qualitative research

1. Introduction

A vertical or horizontal networking of health professionals (HP) along a care pathway can build an integrative structure to improve the continuity of care (CoC) and the quality of care (QoC) [1-3]. The need for integration is especially given for the increasing number of elderly multi-morbid patients with chronic diseases [4]. The chronic wound is also one of these diseases. In Germany alone, studies demonstrate that more than 890,000 predominantly elderly people suffer from chronic wounds, almost 85% of them suffering multi-morbidity [5]. To better coordinate wound care for the benefit of the patient and to increase the CoC, many HP voluntarily form so-called interprofessional wound networks (IPWN) [2]. According to our research over 90 such IPWNs exist in Germany. However, the number fluctuates due to persistent new foundations and dissolutions.

To ensure the information continuity as part of the CoC [6], the implementation of health IT systems (HIT) in a network is seen as a key enabling factor, which also has directly or indirectly an effect on QoC [1,4,7]. Networks of HP with existing social

¹ Corresponding Author, Osnabrück University of Applied Sciences, Kaiserstr. 10c, 49809 Lingen, Germany; E-mail: o.teckert@hs-osnabrueck.de.

relationships represent a solid basis for the implementation and use of a shared HIT [8]. A first analysis of the wound networks reveals that an IPWN alone is not sufficient for establishing an electronic network for the benefit of the wound patients. To this end, freely accessible online data material on 37 of these IPWNs was compiled and searched for key terms such as electronic, digital or IT using MAXQDA. Only nine networks had information on the topic of electronic networking, which does not mean that a shared HIT is actually employed.

For this reason, this study aims to examine the barriers why these IPWN do not take the next step by trying to increase the information continuity through a shared HIT and possible approaches how to overcome these barriers.

2. Methods

Numerous studies deal with barriers to IT use in the health sector. However, these are usually limited to individual medical specializations or institutions. Furthermore, these studies are suitable as a starting point but do not allow for differentiated insights into IPWN. For this reason, we chose a qualitative approach applying guideline-based expert interviews, prompting network managers to report on their experiences with HIT in IPWN. As these interviews were carried out in the context of an overarching project, we also asked questions on other network-specific topics that are not part of this study.

Selected main contacts (e.g. named as managers, coordinators, speakers, chairmen) of IPWN were written to, contacted by telephone or addressed at wound congresses. All together 11 experts (two physicians, three nurses/wound manager, two medical supplier/pharmacist, three managing directors of a management company with a medical background and one other HP) could thus be recruited. These experts are managing 13 wound networks that are under closer examination. The interviews were conducted face-to-face between April and September 2018 and lasted from 74 to 130 minutes each (Ø 104 minutes).

Nine of the networks are a non-profit association. Four networks do not have their own legal form, of which two are publicly funded project networks. In addition, one network is organized as an ICW² working group. All networks are multiprofessional. With the exception of one network, the connectivity is intersectoral. Only two of the networks label themselves as supraregionally active networks.

All interviews were recorded and transcribed. The evaluation was framed by a deductive-inductive content analysis. For this purpose, we created a deductive category system. This system was inductively expanded throughout the course of the analysis [9].

3. Results

According to the experts, only one network never raised the issue of a HIT application. In the other 12 IPWNs this was at least discussed, and in five networks an electronic patient record (EPR) was finally introduced. In two IPWNs the HIT application was discontinued after the test phase. In another IPWN HIT was not used at all, and in the other two IPWN

² The Initiative Chronische Wunden e.V. [Initiative Chronic Wounds] was launched in 1995 by physicians, nurses and other activists in order to improve the prevention and treatment of people with chronic wounds. URL: <https://www.icwunden.de/da/about-us.html>

the EPR is currently used by at least one network member, even while use falls short of expectations. The experts agree that HIT can support networking in various ways. A number of network activities that go beyond general personal information exchange or joint training activities are only made possible by this. However, what are the reasons for either not implementing a HIT or for a limited use? In the course of the content analysis, we initially defined four main topics inductively as possible categories of barriers: A) personal, B) financial, C) technical and D) legal [10]. The subcodes, as displayed in Table 1, were defined inductively.

Table 1. Barriers of a HIT application: list of defined codes and subcodes

Code	Subcode
A Personal	Heterogeneity of the actors (requirements, demands, goals)
	Doubts about the advantages
	Holding on to the tried and tested
	Fear of control of other network members/restriction of autonomy to act
	Lack of trust in data of other network members
B Financial	Lack of technical affinity and competence
	Investments in hardware and software
	Financial losses due to additional time expenditure
C Technical	Financial losses due to the discontinuation of medical examinations
	Missing interfaces / interoperability
	Missing network coverage
	Missing hardware equipment
D Legal	Lack of technical support

Category A: Personal barriers are mentioned by all experts without exception. The *heterogeneity of the actors* requires different needs, demands and objectives in relationship to HIT. In addition, the HP have *doubts about the advantages* of an EPR. “The system itself, the communication platform itself, does neither unite the network nor does it result in higher quality. If I have not defined quality beforehand, it will not be complied with. It can only be a means to an end and will be accepted wherever I really see it. I have been logging it with a lot of effort so far, and now I press a button and it is easier.” (Managing director 2) Many HP prefer to *hold on to the tried and tested* because a new HIT always means a change in individual working methods and routines. Older network members, in particular, are generally skeptical about new digital applications. A *feared restriction of the autonomy to act* and the *fear of control by other members* “[can] be so negative that people always have the feeling that we are always looking into their cards. And that everyone would rather do their own thing” (Nurse 1). In addition, a *lack of trust in the data of other HP* may prevent the introduction of a HIT. A *lack of technical affinity and competence* also means that for many nurses and physicians the topic is “a book with seven seals” (Managing Director 1). Hence, it receives little attention in voluntary wound networks.

Category B: Financial barriers are among the most frequently mentioned barriers in the literature [10]. The experts allude *investments in necessary hardware and software*. Moreover, a new HIT can also result in running costs, for instance, for support. A possible interface to existing IT systems in order to establish interoperability and avoid double documentation is also described as very costly. HP fear *financial losses due to additional time*, if the new system must be used in parallel with existing systems. Fears of *financial losses due to the elimination of medical examinations* due to electronic exchange are also mentioned. Eventually, double examinations represent a source of income for HP.

Category C: Technical barriers result from a *lack of interfaces or interoperability*. “To dare the next step: I hook up there, just pick up something and can even write something in there. That does not work! The office-based physician asks: how can that enter my practice management software system? Not at all! The hospital doctor in the ambulance asks: how do I recognize it? Neither, because these are all structures that do not belong together, and do not belong together intentionally.” (Managing director 2) Inadequate reception quality - for example in areas with a *low network coverage* - and poor or *missing hardware equipment* on the part of the members make IT networking impossible. A *lack of technical support*, e.g. by a software company, can also delineate a potential usage barrier.

Category D: Legal issues. *Data protection* is a sensitive issue, especially in the healthcare sector. Doubts as to whether highly sensitive patient-related data are secure with other users and are not misused are a potential barrier.

4. Discussion

The exploratory research demonstrates that interconnectedness of HP alone does not pave the way for the implementation and use of health IT. Similarly, none of the networks considered can be highlighted as the best case.

According to the experts, an attempt to overcome the barriers described in the categories A-D separately would be insufficient. This is due to the interconnectedness of the barriers and the difficulty to gain direct impact on them [10]. This can be illustrated by several examples: some of the experts complain about the lacking financial support for a HIT, which impairs the funding of such a project. However, the costs alone cannot determine the lack of software introduction and application. For example, the HIT in one of the IPWN was financed by public project funds, and the use was free of charge for the actors involved. Nevertheless, it was hardly used or completely rejected. Four other experts report a similar situation, where the software and some of the hardware were offered to network members free of charge or for only a small fee. However, in the end the expected success failed to emerge. In the case of all these networks, the HIT was even developed internally or selected together with the members for the sake of diversity of the actors. Despite initial euphoria, training courses to harmonize wound care and increase technical competence did not result in the desired use.

Overcoming the barriers is a complex process and requires a holistic concept and support from various actors. Voluntarily formed networks themselves cannot guarantee information continuity. “After all, a network is also a bottom-up movement, if you like. It is professionally triggered, it is largely care-triggered but does not solve the system problem in this way”. (Managing director 2)

The establishment of a network and the topic of HIT depend too much on the commitment of individual HPs. Once the networking and implementation of HIT succeed, then only isolated solutions are created. The experts see a particular duty on politicians, who should not only provide the financial means for individual pilot projects. They must also accompany and coordinate networking at a regional level in terms of its content. According to the experts, this includes creating discussion platforms and structural guidelines for cooperation and communication in networks and, above all, defining nationally binding processes and standards in wound care that are mapped in a mandatory and central HIT. Instead of an individual obligation to provide evidence, it might also help

to enable an integrative consideration of services. This study is limited due to the small sample size. In addition, the findings are confined to wound networks and cannot be readily generalized to other health networks. Evaluating the impact of the structure and the quality of the networks on HIT usage is subject for future work [11].

5. Conclusion

The study demonstrates that networks of HP cannot guarantee information continuity. The experiences of 11 managers reveal that, despite the voluntary structures created, there are numerous barriers to a HIT implementation and use. The overcoming of these barriers should not be left to the commitment and voluntariness of individual HPs but should be actively controlled by policymakers. In this way, QoC can be improved by HIT used across institutions [3].

Abstract Hospitalization expenses account for a high proportion of national medical care expenditure in Japan. In 2015, the total national medical care expenditure in Japan was 42.4 trillion yen, and hospitalization expenses were 15.6 trillion yen (36.8%). Therefore, it is necessary to reduce hospitalization expenses. The labor cost of physicians and nurses accounted for about 1/3rd of all expenditure of general hospitals in 2015. Moreover, the personnel cost of nurses accounted for about 1/5th of all expenditure, indicating that it has a marked impact on hospital management. Nurses spend a lot of time completing descriptive records; however, the quality of such records is poor. It is necessary to improve nurse's records to make them highly accessible and reduce the amount of time nurses spend producing records. The objective of this study was to improve the processes underlying record-keeping by nurses in order to harmonize structured clinical knowledge among doctors and nurses. We created 778 Patient Condition Adaptive Path System (PCAPS) items, covering all of the clinical departments that were registered for the PCAPS content master. The resultant masters will be standardized by sharing them with hospitals that adopt the "Team Compass" application. We were able to summarize all of the information in clinical progress sheets because we could link the information described in electronic medical records with that described in Team Compass. Therefore, it became easy to collect information by linking information about clinical orders. The system also made it possible for foundational nursing plans to be created in collaboration with doctors instead of being developed by nurses alone because it allowed information regarding patients' problems, the clinical process, and observation selection to be shared smoothly with doctors. We implemented Team Compass in May 2019. On the first day, PCAPS-based care pathways were used to treat 580 of 623 inpatients. Approximately 4,000 patients were treated using this system from May to August 2019. No major problems have arisen since the implementation of Team Compass.

Keywords: digitalization, quality management, healthcare, structured clinical knowledge

1. Introduction

Hospitalization expenses account for a high proportion of national medical care expenditure in Japan. In 2015, the total national medical care expenditure in Japan was 42.4 trillion yen, and hospitalization expenses were 15.6 trillion yen (36.8%). Therefore, it is necessary to take measures to reduce hospitalization expenses. The total labor cost

of physicians and nurses accounted for about 1/3rd of all expenditure of general hospitals in 2015 [1–3]. Moreover, the personnel cost of nurses accounted for about 1/5th of all expenditure, indicating that it has a marked impact on hospital management.

Nurses spend a lot of time producing records. Specifically, nurses produce descriptive records; however, the quality of such records is poor. Therefore, it is necessary to improve record-keeping systems to make nurse's records easily accessible and reduce the time nurses spend producing records. In a survey evaluating the quality of nursing records, Tsuru et al. suggested that <50% of the patient observations required to deal with individual patients were recorded by nurses. In addition, failures in planning, implementation, and recording have been identified in nursing care in Japan [4–6]. Moreover, it was clarified that data production and input depend on individual nurses, and many observations are recorded in descriptive electronic records, which can be difficult for other staff members to interpret.

To solve planning failures, the preparation and utilization of many high-quality models of treatment and nursing care plans is useful. Thus, we have developed a structured clinical knowledgebase by incorporating the Navigator for Thinking Processes in Nursing (NursingNAVI™) into the Patient Condition Adaptive Path System™ (PCAPS) [7–9].

During this process, structured nursing care plans were developed using the Standard Terminology for Nursing Observation and Action (Ministry of Health, Labour Standards since 2016) for electronic medical records (EMR). Then, an application for supporting the recording of structured nursing care plans was designed and implemented at a large-scale acute-care hospital with 1,000 beds. As a result, the proportion of nurses who took ≥ 30 minutes to identify the conditions of patients in their charge decreased from 45.4% to 5% within 3 months. It was suggested that the utilization of high-quality structured nursing care plans based on clinical nursing knowledge supports the thinking processes of nurses and reduces the time they require to complete their work. After 3 years, the amount of overtime being performed in the hospital had markedly decreased, and almost no overtime was being used to complete records [9].

In Japan, to improve the efficiency of medical care services, the development of an information system to support medical fee payment was initiated in the 1980s, and the development and introduction of a hospital information system (an EMR system) that could record instructions and the execution of tests and treatments was initiated in 2000. Since then, the use of EMR systems has increased, and they have become essential for medical fee payment. In hospitals that use a comprehensive payment system termed DPC, the system records data about any medical care provided, leading to an era of big data in medical care. However, there is a problem with the quality of the data included in EMR, and a survey performed by Yahagi et al. suggested that such records are a long way from being useful for clinical evaluations. It was considered that the development of a new EMR system is necessary to allow analyses of the relationship between hospital management and clinical quality.

Thus, we decided to develop an operational support system that could be used to manage a larger amount of structured clinical knowledge and support routine work.

Since medical care is provided by many departments, 24 hours a day, 365 days a year, it was decided that the system would have to possess the following functions: (1) It should not change existing tests or treatment work and (2) should improve the quality, recording, and execution efficiency of nursing plans.

2. Implementation method

2.1. Development of the ‘Team Compass’ application

We developed ‘Team Compass’ as an application for PCAPS [7–9]. Team Compass has many functions that support the work processes of nurses and doctors. We implemented the first system, which we developed at an acute care hospital with 300 beds, at a university hospital with 900 beds. We listened to the demands of nurses with regard to the functions they wanted and pushed forward with developing these functions. We adopted the following rule to ensure patient safety: Patients’ data should be recorded in both their EMR and the Team Compass system. Therefore, we decided on the following procedure: First, a nurse should enter a patient’s data into their EMR. Then, they should transfer the data to Team Compass.

- 1. A medical doctor orders PCAPS items for each patient from their.
- 2. A nurse opens the EMR system and selects the patient.
- 3. When the nurse clicks the ‘PCAPS’ button, the PCAPS items for the patient are.
- 4. The nurse is able to understand the patient’s condition, and starts their work.

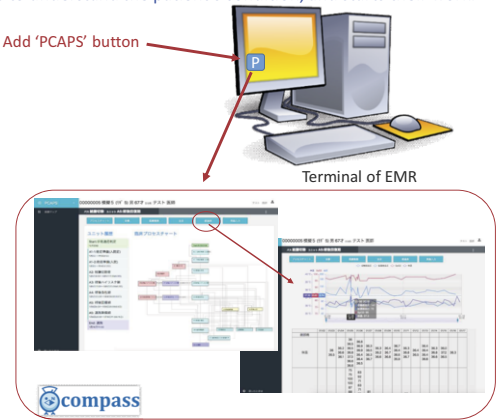

Figure 1. Functions and rules used to ensure patient safety during the use of EMR and Team Compass

2.2. Development of care pathways using PCAPSTM and NursingNAVITM

We interviewed doctors from each clinical department and classified structured treatments into four categories: surgery, internal medicine, short admissions, and one unit. In addition, we linked problems described in the medical task order sheet and Team Compass to share information with doctors, and we constructed a system in which nursing plans are created automatically without checking orders from doctors. We created nursing plans using masters related to surgery and other treatments, which were collaboratively created by doctors and nurses. We used the PCAPS content master developed by the University of Tokyo as the basis for these masters. Also, nursing care and observations completely followed the nursing practice standard masters of the Ministry of Health, Labour and Welfare.

We created 778 PCAPS items, which covered all of the clinical departments that were registered for the PCAPS content master. These masters will be standardized by sharing them with hospitals that adopt Team Compass. We were able to summarize all of the information in patients' clinical progress sheets because we linked the information described in the patients' EMR with that in Team Compass. Therefore, it became easy to collect information by linking information about clinical orders.

The system also made it possible for foundational nursing plans to be created in collaboration with doctors instead of being developed by nurses alone because it allowed information regarding patients' problems, the clinical process, and the selection of observations to be shared smoothly with doctors. In the future, we aim to develop a more sophisticated system that manages the support of patients and reduces the burden of nursing tasks.

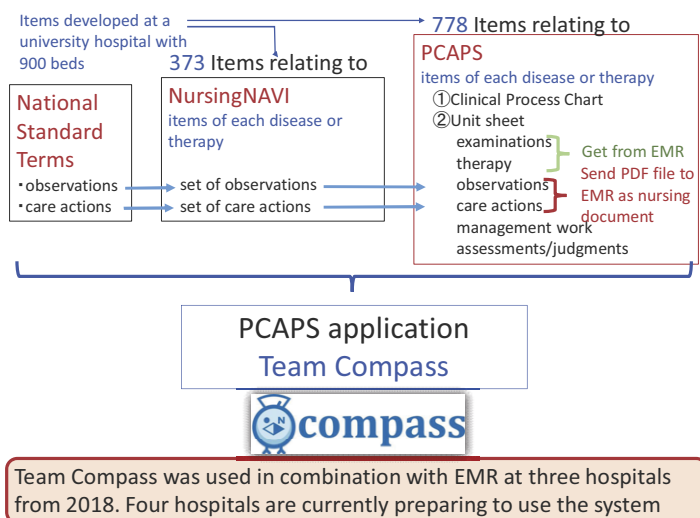

Figure 2. Structured clinical knowledge relating to National Standard Terms for Nursing Practice, NursingNAVI, and PCAPS

3. Results

We implemented Team Compass in May 2019. On the first day, PCAPS-based care was provided to 580 of 623 inpatients. Approximately 4,000 patients were treated using PCAPS from May to August 2019. There were no major problems after the implementation of the system.

The description record of the nurse decreases sharply and, as a structured record, can see it with a progress table. The way of working of the nurse changed. First, they take charge and grasp the summary of the patient from process chart. Secondary, they obtain detailed information with a progress table. The structured record of the nursing is stored within EMR as a PDF file every day in AM at 5:00.

The change of the patient state is detected by a unit shift in the process chart and event occurrence information. The change is shared with a doctor in nurses. The team care between doctor and nurses became in this way smoother.

Nurses handling duties effectively can realize real-time input, and over hours decreases. However, the nurse whom over hours cannot yet shorten exists. We analyze the causes.

4. Discussion

Our system successfully harmonized structured clinical knowledge among medical doctors and nurses. The improvement of record-keeping by nurses at our university hospital has started. We are developing an evaluation system for quality improvement. In the near future, we will implement the evaluation system and advance quality improvement at our hospital.

Acknowledgements

We are deeply grateful for the collaboration of the project members and organizations. This work was supported by JSPS KAKENHI (Grant-in-Aid for Scientific Research) No. 17H01608.

Physicians' Experiences of Patient-Initiated Online Consultations in Primary Care Using Direct-To-Consumer Technology

Sabine KOCH^{a,1} and Miwa GUHRES^a

^a*Health Informatics Centre, Department of Learning, Informatics, Management and Ethics, Karolinska Institutet, Stockholm, Sweden*

Abstract. Both private and public primary healthcare providers increasingly offer their patients online consultation services on request. However, the actual use of these services from a physician's perspective as well as the educational competencies required by the physicians are insufficiently studied. The aim of this study is therefore to explore how general practitioners (GPs) experience video consultations with patients compared to physical consultations in primary care in Sweden. We performed a web-based survey amongst 32 GPs. Despite the advantage of being perceived as time saving, more than half of the physicians did not agree that video consultations are more effective than physical consultations. Most physicians had a positive attitude towards the use of video consultations in their work but reliability of the technical platform was considered to be essential, younger physicians should have worked with physical consultations prior to working with online consultations and the use of (semi-) automatic triage systems was wanted when patients themselves can book appointments for online consultations.

Keywords. Digital visit, online consultation, video consultation, primary care

1. Introduction

Recently the use of mobile technologies related to healthcare delivery has experienced a rapid growth. Direct communication between a healthcare professional and a patient at home or work, so called Direct-to-Consumer (DTC) telemedicine gives patients quick and convenient access to a healthcare professional [1].

In primary care the feasibility and acceptance of utilization of healthcare-initiated telemedicine is supported by many studies and is often more acceptable to patients than healthcare professionals [2]. There are however limited studies about how physicians perceive patient-initiated video consultations. Most studies [3-5] focused on the patients' experience and their satisfaction with using video consultation. Some studies on video consultation investigated physicians' perceptions showing that participants were positive to the use of video consultations in general [6] and elicited potential benefits to use video consultation in primary care [7]. However, at the same time participants felt it should not be used as a substitute for physical consultation and some

¹ Corresponding Author: Prof. Dr. Sabine Koch, Health Informatics Centre, LIME, Karolinska Institutet, Stockholm, Sweden; e-mail: sabine.koch@ki.se

GPs were concerned about the possibility that video consultations would prevent younger physicians from getting clinical experience [7].

In Sweden both public and private care providers have delivered a variety of digital care services and the number of patient-initiated digital visits to physicians is increasing rapidly. Physicians in Sweden have raised concerns regarding their work environment, patient safety and healthcare priorities which have been partly analysed at a smaller scale [8]. Nevertheless, studies of video consultation from a physician's perspective are limited and there is a lack of knowledge about how video consultations are adopted by GPs compared to physical consultations.

Therefore this study aims to explore how general practitioners (GPs) experience video consultations with patients compared to physical consultations in primary care in Sweden.

2. Methods

Data was collected through a web-based survey targeting general practitioners (n=32) in Sweden using exploratory and snowball sampling. The questionnaire consisted of 28 statements to be rated by the GPs on a five-point Likert scale [do not agree at all...completely agree]. The statements were structured according to eight categories; 1. Background, 2. Accessibility, 3. Consultation, 4. Communication, 5. Competence, Education, 6. Care delivery structure, 7. Technology and 8. Open-ended questions regarding the advantages and challenges of video consultation and the competencies needed for physicians in video consultation.

A link to the questionnaire was sent by e-mail to representatives of organizations that offer online video consultations to their patients and to the Swedish Medical Association.

Respondents signed an informed consent when contributing to the study, the data was treated anonymously and was used for research purposes only.

Microsoft Excel and R were used to analyze and visualize quantitative data from the questionnaire. Microsoft Excel and KH Coder were used to analyze and visualize free text/qualitative data.

3. Results

The total number of respondents was 32 with an average age of 42.8 years and the ratio of males to females was 56% and 44%. The average years of experience as GP was 9.6 years. 19 respondents had less than 10 years of experience and 2 respondents had more than 20 years of the experience. The average of years of experience doing video consultation was 1.3 years. The ratio of private, public and both private and public organizations where GPs worked with video consultation was 16%, 78% and 6% respectively. The respondents belonged to 10 different organizations.

28 respondents had access to the patient's health record during video consultations in the same way that they had during physical consultations, four respondents did not. Two third of the respondents (n=22) received education about how to communicate with the patient during video consultations, one third (n=10) did not. The average length of video consultation's time (9.3minutes) was shorter than physical consultation's time (20.8 minutes). Only 1 respondent stated the same length for both

video and physical consultations. All respondents worked with both physical and video consultations, on average 14% of fulltime work was devoted to video consultations.

3.1. Comparison of physical versus video consultations

There was a strong agreement among the respondents that *video consultations give patients faster access to healthcare* [AVG: 4.4; SD: 1.26]², *provide high flexibility to patients* [AVG: 4.3; SD: 0.84], *decrease travel time and costs for patients* [AVG: 4.3; SD: 1.26] and *increase accessibility for persons with functional disabilities* [AVG: 4.1; SD: 1.14]. The respondents were indecisive whether *video consultations increase accessibility for patients with chronic diseases* [AVG: 2.8; SD: 1.70].

The respondents considered *information for decision making during video consultations to be limited compared to physical consultations* [AVG: 4.1; SD: 0.78] but a majority agreed that *video consultations however influence their working environment in a positive way* [AVG: 3.9; SD: 1.27], e.g. through higher flexibility. They were indecisive, however, if *video consultations reduce their workload* [AVG: 3.1; SD: 1.45] and most respondents did not think that *video consultations are more effective than physical consultations* [AVG: 2.2; SD: 1.01]. Also, a slight majority did not *feel comfortable referring patients from a video consultation directly to secondary care* [AVG: 2.8; SD: 1.35].

The respondents were indecisive whether *communication with the patient works as good during a video consultation as during a physical consultation* [AVG: 3.4; SD: 1.27] and whether *GPs need to get extra education about communication and need extra skills when doing video consultations* [AVG: 3.3; SD: 1.13]. The respondents however strongly agreed that *younger physicians need to get clinical experience from physical consultations prior to working with video consultations* [AVG: 4.6; SD: 0.86]. In general, few respondents were *concerned about patients recording the video consultations* [AVG: 1.7; SD: 0.85]. There was not much agreement among the respondents if they *lose the personal contact with the patient during a video consultation* [AVG: 2.8; SD: 1.45].

The respondents further strongly agreed that *a (semi)-automatic triage system needs to be in place* that would guide patients to the right level of care [AVG: 3.9; SD: 1.29] and respondents tended to agree that *it is possible to predict which patient is appropriate for video consultation by analyzing the medical history* [AVG: 3.2; SD: 0.96]. There was also a strong agreement among the respondents that the *technology for video consultations is easy to use* [AVG: 4.2; SD: 0.85] and its *quality (sound, image, reliability of the connection) is good enough* [AVG: 3.9; SD: 0.98].

3.2. Advantages of video consultations

Time efficiency, flexibility regarding working hours and working from home as well as improved working conditions and opportunities for clinical consulting were mentioned as advantages of video consultations.

² Text in this section resembles the statements from the questionnaire that were rated on a five-point Likert scale [do not agree at all...completely agree]. This example: *Video consultations give patients faster access to healthcare* (= Statement); AVG = average Likert value; SD = standard deviation

Time efficiency was supported in the free-text analyses by quotes such as “I get time to meet more patients”, “I meet many patients and can help them urgently” or “Digital visits give a better structure for how the consultation time is used in an efficient way”.

Respondents also pointed out the flexibility of the work specifically by expressing opinions such as “Video consultations give more flexibility for me as physician”, “Flexibility to work from home” and “Flexibility regarding working time”.

They further mentioned advantages regarding their work environment such as “New experience that you would need in case of a general digitalization that you cannot avoid”, “Stimulating and challenging to work in a different way”, “It is very good to be able to follow your own patients”, “Reach patients who are unable to get to the clinic themselves”, and “That patients who are not very sick do not take time slots on the clinics”.

Respondents also discussed video consultations vs phone consultations in their free-text answers exemplifying additional benefits such as “Visual contact is a complement to contact over the phone”, “For example, when dealing with psychiatric disease or skin disease, it is better to have video contact with the patient compared to using phone” and “Gives somewhat more information than a phone call”.

3.3. Challenges of video consultations

The respondents considered it to be challenging to guide the right patients to video consultations, i.e. they should not require a physical examination. This was clearly articulated in free-text answers such as “Need to find the right way in which patients and conditions can best be managed” and “To deselect patients who do not need medical assessment in order to save on healthcare resources”. Further, other forms of digital communication were proposed in some cases - “A lot of consultations can be made with chat not requiring video consultation”. Automatic triage systems were seen as a possible solution to guide patients to the right level of care - “Faster and safer consultations with AI-triage in place”.

Respondents also reported about high expectations and a poor understanding by patients of what can be handled during a video consultation. This is supported by statements such as “Wrong patients are looking for video meetings and they are not those with disabilities but those who are in a hurry in everyday life”, “Some patients have a poor understanding of what can be handled digitally” and “Without triage patients are to a large extent looking for things that are obviously not suitable for video visits”.

Further challenges mentioned by the respondents include the lack of a continuous relationship between physician and patient, the lack of an automatic system for patient triage, the lack of accessibility to integrate with physical care, and the necessity to adapt the current reimbursement model.

4. Discussion and conclusion

The respondents of this study were in general very positive to video consultations. The main advantages mentioned were GPs' flexibility regarding time and working place, increased accessibility for patients and time efficiency for both physicians and patients which is in line with other studies [7-10]. 59% of the respondents were of the

opinion that the lack of a physical examination makes the assessment of the patient insecure during video consultations. This is comparable with the results by Randhawa et al [7] who found that many GPs thought the lack of physical examination was a drawback in video consultations and the assessment of the patient became somewhat incomplete.

The main challenges of video consultations were to find a way to guide the patients to the appropriate consultation that matched with their conditions and the limited information for decision making in video consultations compared to physical consultations. It was considered necessary to introduce a (semi)-automatic triage system before video consultations.

The respondents were indecisive regarding the need to get extra education and need extra skills when doing video consultations. Nevertheless, skills related to digital technology certainly need to be introduced into physicians' educational programs which is also confirmed by a study by Jiwa and Meng [6] who considered video consultation techniques to be required to be learned by medical students in undergraduate education.

In conclusion, most physicians had a positive attitude towards the use of video consultations in their work but reliability of the technical platform was considered to be essential, younger physicians should have worked with physical consultations prior to working with online consultations and the use of (semi-) automatic triage systems was wanted when patients themselves can book appointments for online consultations.

PM-TOM: A Method for Finding Personalized Polypharmacy Therapies with Minimal Adverse Drug-Drug, Drug-Gene and Drug-Condition Interactions

Adnan KULENOVIC^{a,1} and Azra LAGUMDZIJA-KULENOVIC^a

^a A ! A – Absolute Information Age, Inc. Toronto, Canada.

Abstract. Polypharmacy therapies, quite frequent in older populations, pose significant health risks for patients due to a high possibility of their cumulative adverse drug reactions. We present Personalized Medicine Therapy Optimization Method (PM-TOM) for the discovery of polypharmacy therapies with minimal drug-drug interactions, drug-gene interactions, and drug-condition interactions. The inputs of the PM-TOM heuristic algorithm are the patient's conditions, genome, and the drug products and therapy considered by a clinician. Its output is a comprehensive report that explains details of the optimal therapies for considered drug products and all drugs that treat the patient's conditions. PM-TOM was developed by using the Electronic Medical Records repository of the Personal Genome Project (PGP), and the public repositories: DrugBank and Comprehensive Toxicogenomics Database (CTD). Testing of PM-TOM showed potential for significant reduction of the cumulative adverse drug interactions in personalized polypharmacy therapies. In the group of patients with 8 to 17 conditions, PM-TOM reduced the average cumulative drug interactions from 22 to 5.83, and the group with 6 to 7 conditions from 11.17 to 3. These results encourage further research and development of clinical decision support tools like PM-TOM.

Keywords. Personalized Medicine, Electronic Medical Records, Polypharmacy Therapies, Clinical Decision Support, Adverse Drug Reactions, Drug-Drug Interactions, Drug-Gene Interactions, Drug-Condition Interactions.

1. Introduction

Multiple studies show that polypharmacy therapies can lead to dangerous adverse drug reactions (*ADR*) and high healthcare costs due to their cumulative drug-drug interactions (*DDI*), drug-gene interactions (*DGI*), and contraindicated drug-condition interactions (*DCI*). Paper [1] reports that the average patient in the examined cohort was prescribed with 12 medications; significant *DGIs* were found in 73% of tested patients and *DDIs* in 87% of patients. In the study explained in paper [2], *DDIs* accounted for 66.1% of the total interactions, and the remaining 33.9% were *DGIs*. In Canada, among patients aged 65 years and older with polypharmacy (>5 drugs) admitted to hospital, the prevalence of potential drug interactions is 80% [3]. The study described in the paper [4] states that in 1994 some 2,216,000 hospitalized patients had

¹ Corresponding Author, Adnan Kulenovic, E-mail: A.Kulenovic@rogers.com

severe *ADRs* with 106,000 fatal outcomes, making these reactions between the fourth and sixth leading cause of death in the US that year.

Our research is motivated by the urgency of finding solutions to these troubling facts. In this paper, we present the Personalized Medicine Therapy Optimization Method (*PM-TOM*) for the discovery of polypharmacy therapies with minimal *DDIs*, *DGIs*, and *DCIs* (referred to in the paper as cumulative adverse interactions - *CADIs*). In Section 2, we explain the inputs, outputs, and the database of the *PM-TOM* method, and in Section 3, its heuristic algorithm. In the development, testing, and validation of *PM-TOM*, we used the public data repositories of the *Personal Genome Project* (*PGP*) [5], *DrugBank* [6], and *Comparative Toxicogenomics Database* (*CTD*) [7]. Results, presented in Section 4, show that *PM-TOM* has the potential to aid in the significant reduction of the cumulative drug interactions in polypharmacy therapies.

2. PM-TOM Database, Inputs and Outputs

The components of the ***PM-TOM* database** are (i) Electronic Medical Records (*EMR*) repository (denoted as *EMR*), (ii) Drug Repository (*DRG*), and (iii) Gene-Drug Repository (*GDR*). The current version of *PM-TOM* requires from *EMR* only the patient conditions, drug product prescriptions, and genome (gene variations that could be pathogenic or affect drug behavior, i.e., found to be pharmacogenetic). Other *EMR* elements, such as the patient's gender, race, blood type, drug dosages, etc., will be used in the future *PM-TOM* versions. Formally, $EMR \subset PID \times \mathbb{P}(C) \times \mathbb{P}(G) \times \mathbb{P}(P)$, where *PID* is a set of patient IDs, *C* the set of all conditions, *G* the set of all genes and their variants, *P* set of all commercial drug products, and \mathbb{P} powerset symbol.

The drug repository (*DRG*) includes data about the active drug ingredients (referred to as “drugs” in this paper), commercial drug products (referred to as “drug products”), drug-drug interactions, and drug-condition contraindications. The database keeps drug interactions by referencing active drug ingredients (drugs) rather than drug products. If *D* denotes the set of all drugs, then the set of drug products *P* can be defined as $P \subset D \times N$ (*N* is the set of product names). Set *DC* describes the drug indications, $DC \subset D \times C$. Set $DDI \subset D \times D \times DDS$ defines the drug-drug interactions, where set $DDS = \{1, 2, \dots\}$ quantifies their relative severities. Similarly, set $DCI \subset D \times C \times DCS$ describes the drug contraindications, where set *DCS* quantifies their severities. Gene-Drug Repository (*GDR*) keeps data about drug-gene interactions and their severities, denoted as set $DGI \subset D \times G \times DGS$ (*DGS* is a set of their severities).

***PM-TOM* inputs** include a patient's (i) conditions, (ii) considered drug products, (iii) genome, and (iv) the initial therapy, which is composed of a single drug product for each condition. Formally, the input *PM-TOM* record is $r_i = (pid_i, C_i, G_i, P_i, t_i)$, where $pid_i \in PID$; C_i is the set of the patient's conditions, $C_i \subset C$; G_i is the patient's genome, $G_i \subset G$; P_i is the set of considered drug products, $P_i \subset P$; and t_i is the initial therapy, $t_i \subset C \times P_i$.

***PM-TOM* outputs** are (i) optimal therapy for considered drug products, *tc*, (ii) optimal therapy for all drugs, *to*, which *PM-TOM* creates after examining all drugs from *EMR* applicable to the patient's conditions, and (iii) a detailed personalized therapy report. The report elaborates both optimal therapies, indicating their *CADIs*, and explaining their drug-drug, drug-gene, and drug-condition interactions. It also includes the list of all available drug products for each drug suggested in *to*.

3. PM-TOM Algorithm

In Step 1, *PM-TOM* collects the patient's record. An example is a *PGP* record with patient's *ID* = 'huC29627'; conditions $C_i = \{Anxiety, ADHD, Depression\}$; genome $G_i = \{CBS, TGM1, MBL2, C3, BRCA2, COL41A, TP53, ITPA, KCNH2, DRD2, MBL2, CACNA1C\}$; considered drug products $P_i = \{Venlafaxine, Xanax, Zoloft, Escitalopram, Adderall, Ritalin, Celexa, Wellbutrin, Viibryd\}$; and the initial therapy $t_i = \{(Anxiety, Zoloft), (ADHD, Adderall), (Depression, Celexa)\}$.

PM-TOM identifies, in Step 2, the corresponding drug (drug ingredient) of each considered drug product. For example, the active drug ingredient of *Xanax* is *Alprazolam*. Next, as Step 3, *PM-TOM* prepares the set of pairs of conditions and considered drug products, called CD_i . In the above example, $CD_i = \{(Anxiety, Venlafaxine), (Anxiety, Xanax), (Anxiety, Escitalopram), (Anxiety, Zoloft)^*, (ADHD, Adderall)^*, (ADHD, Ritalin), (Depression, Celexa)^*, (Depression, Viibryd), (Depression, Wellbutrin)\}$. The pairs marked with * indicate the initial therapy (t_i).

In Step 4, *PM-TOM* uses set CD_i to identify candidate therapies, t_k , for considered drug products. It forms candidate therapies by replacing only one drug in the initial therapy with another drug from set CD_i applicable to the same condition. An example of a candidate therapy is $\{(Anxiety, Xanax), (ADHD, Adderall)^*, (Depression, Celexa)^*\}$, i.e., for *Anxiety*, *Xanax* replaced *Zoloft*. Note that *PM-TOM* does not evaluate all combinations of considered drug products so that it could miss the most effective therapy. However, the testing results show that this approach can lead to significant improvements in the initial treatments. If d is the average number of candidate drugs for n conditions, then the complexity of an algorithm that evaluates all drug combinations will be proportional to d^n . *PM-TOM* examines only $n*d$ candidate therapies.

In Step 5, *PM-TOM* calculates *CADI* indicator (w) of each candidate therapy t_k after examining the following sets: (i) drug-drug interactions $DDI_k = \{ddi_k = (d_1, d_2, dds): \exists(c_1, d_1) \in t_k, \exists(c_2, d_2) \in t_k, ddi_k \in DDI\}$, (ii) drug-gene interactions $DGI_k = \{dgi_k = (d, g, dgs): \exists(c, d) \in t_k, g \in G_i, dgi_k \in DGI\}$, and (iii) drug-condition contraindications $DCI_k = \{dci_k = (d, c, dcs): \exists(c_1, d) \in t_k, \exists(c, d_1) \in t_k, \nexists(c_1, d_1) \in t_k, dci_k \in DCI\}$. $w(t_k)$ is calculated as

$$w(t_k) = DDIP * \sum_{ddi_k \in DDI_k} ddi_k[dds] + DGIP * \sum_{dgi_k \in DGI_k} dgi_k[dgs] + DCIP * \sum_{dci_k \in DCI_k} dci_k[dcs]. \quad (1)$$

DDIP, *DGIP*, and *DDIP* are the *PM-TOM* parameters that define relative weights of *DDIs*, *DGIs*, and *DCIs* (set to 1 by default). $ddi_k[dds]$, $dgi_k[dgs]$, and $dci_k[dcs]$ indicate severities of these interactions. As an example, the *CADI* indicator of the above initial therapy is $w(t_i) = 6$.

Next, in Step 6, the algorithm iterates through all conditions, and for each condition, finds candidate therapy with minimal *CADI*. In Step 7, *PM-TOM* uses the drugs for each condition that form these candidate therapies to create the optimal therapy for considered drug products. In the above case, the optimal therapy is $t_c = \{(Anxiety, Venlafaxine)^{\#}, (ADHD, Ritalin)^{\#}, (Depression, Celexa)^{\#}\}$, with $w(t_c) = 4$.

As mentioned above, *PM-TOM* is an iterative method. It repeats the above steps, taking the optimal therapy found above as the initial therapy for the next iteration. If the new candidate optimal therapy shows no better $w(t_c)$, the algorithm will stop (Step 8).

In the next phase, *PM-TOM* repeats Steps 3-8 to find the optimal therapy for all drugs (t_o) after (i) collecting all drugs from the *EMR* used to treat the patient's conditions and (ii) taking already found therapy t_c as the starting point, instead of therapy t_i . In the above example, *EMR* returned 33 applicable drugs. t_o was found as $\{(Anxiety, Butabarbital)^{\#}, (ADHD, Dexmethylphenidate\ HCL)^{\#}, (Depression, SAM-E)^{\#}\}$, with $w(t_o)=1$. The report for this *EMR* can be found at <https://www.abs-info-age.com/project-1>.

4. PM-TOM Validation and Testing

In the development, testing, and validation of *PM-TOM*, we used the *EMRs* of *PGP*, which include the patient conditions, genome, and administered drug products. *DrugBank* provided the drug product, drug-condition, and drug-drug interaction data, and *CTD* the drug-gene interaction data. We tested 286 *EMRs*. Table 1 lists in column (A) various categories of tested *EMRs*, which have the same number of conditions. Column (B) shows the count of cases and (C) the average number of genes in each category. Columns (D) and (E) display the average number of considered drug products and all drugs applicable to the patient's conditions.

Table 1. Average *CADI* of the optimal therapies for the considered drugs and all applicable drugs.

(A) Conditions	(B) Cases	(C) Genes	(D) Consid. drugs	(E) All drugs	(F) <i>CADI</i> - Consid. drugs	(G) <i>CADI</i> - All drugs
1	77	13.58	1.31	6.12	0.6	0.09
2	119	5.74	2.34	10.6	1.05	0.22
3	49	3.43	3.51	16.71	2.1	0.33
4	16	4.31	4.38	20.88	3.38	0.56
5	13	4.46	5.92	26	4.92	2.08
6..7	6	2.33	7.33	34	11.17	3
8-	6	10	12.83	42	22	5.83

Columns (F) and (G) display the average *CADIs* of the optimal therapies for considered drug products and all applicable drugs, which indicate a significant reduction of the average *CADI* between these two therapies (approximately three to six times, depending on the category). The algorithm required two iterations (Figure 1).

Figure 1. Average *CADI* for optimal therapies

5. Discussion

In paper [8], the author underlines the need for highly personalized drug selection by expert systems. To the best of our knowledge, *PM-TOM* is an original approach to do so. The testing results presented in Section 4 show that the method can identify possible treatments with significantly decreased *CADIs*. We also tested *EMRs* for some recurrent multi-diseases, like *{Hypertension, Diabetes Mellitus, Hyperlipidemia}*, and their *CADI* reduction was approximately five times. A data mining algorithm for finding frequent multi-diseases, and their possible monogenic causes, is explained in paper [9].

Why do prescribed therapies typically have a high number of drug interactions? We speculate that the reasons are the lack of the patient's genetic data, which would enable finding highly personalized therapies, and the limitations of used tools, which are typically focused on *DDI* alerts. Also, according to the investigation in the US, reported in paper [10], these alerts are overridden for various reasons in about 90% of cases.

PM-TOM is an efficient iterative heuristic algorithm. Its testing confirmed that very few iterations lead to finding therapies with significantly decreased *CADIs*. The algorithm complexity is rather low as it evaluates a small subset of candidate therapies. For example, for seven candidate drugs for 12 conditions, *PM-TOM* will examine only 84 candidate therapies per iteration of possible 14 billion ones. Due to that feature, *PM-TOM* has room for extension with other features relevant for polypharmacy therapies, such as (i) rule-based medical guidelines, (ii) lab test results, (iii) drug dosages, (iv) patient's demographic data (age, race, gender, environment), (v) drug-drug-gene interactions (*DDGIs*), (vi) drug-food interactions, (vii) drug-microbiome interactions, and others.

Abstract. New forms of care for complex chronic diseases require substantial efforts in the collection, storage, and analysis of privacy sensible medical data. Additionally, providing practical support for those who coordinate the actual care management process within a diversified network of regional service providers is beneficial. In this paper, we present a follow-up with the current status, lessons learned, and preliminary results of the IT infrastructure in project STROKE OWL. The project aims at a comprehensive implementation of cross-sector care management for stroke patients. Patients are accompanied in their recovery by stroke pilots, who use a specially designed tablet app for the piloting. It is shown how the tablet app uses receiver-oriented encryption to support the piloting process while ensuring privacy.

Keywords. STROKE OWL, Data Management, Privacy by Design, ROE

1. Introduction

The project STROKE OWL [1] (located in the pilot region Ostwestfalen-Lippe, Germany) aims at a comprehensive implementation of cross-sector care management for patients after a stroke. The actual care management process is carried out by so-called *stroke pilots*, who accompany patients in coordinating their lives after the stroke incident like case managers. In a population-oriented approach, the complete care path is integrated, i.e. the formation and coordination of a network of regional service providers consisting of stroke units, rehabilitation partners, and ambulatory actors, as well as health insurance funds. The primary goal of the project is to measure the change of recurrence rates due to this new care management process.

The mere number and diversity of individual actors (stroke pilots, health insurance funds, study nurses etc.) place high demands on the underlying IT infrastructure of such projects about the collection, provision, and evaluation of data, especially concerning security and privacy. Due to the overall demand for Privacy by Design [2], we proposed a model of comprehensive receiver-oriented encryption (ROE) [3], which we are using in STROKE OWL. In this paper, we show how ROE is practically implemented in the accompanying LotsenApp, a tablet application that supports the stroke pilots in their work with the patients, and how ROE is used in the central data structure. We also present

¹Corresponding Author, email. timo.michelsen@offis.de

a follow-up with an update about the current status, lessons learned with ROE and its implementation in STROKE OWL.

In the following Section 2, we give a brief overview of ROE. Section 3 describes the implementation details of the LotsenApp tablet app and our system architecture motivated by ROE. In Section 4, we give a small overview about some lessons learned during this development. Finally, we conclude with a small status update of STROKE OWL with over 1000 patients and 1 year of app usage.

2. Receiver-oriented encryption (ROE) in STROKE OWL

ROE [3] aims to restrict the access of data recipients using encryption so that only they can access their data and only their data. Especially for medical data it is essential that their accessibility is as limited as possible. To enforce this ROE combines and adapts two existing methods: asymmetric cryptography [4] and pseudonymization.

In STROKE OWL, we realized ROE as follows [3]: stroke pilots gather needed primary data of their accompanied patients. *Primary data* is a combination of personal data (name, address, etc.), domain-specific data (e.g., cross-sectoral medical data from doctors), and case management data for the stroke pilots (e.g., case schedules, assessments, contact network management). The collected primary data is then encrypted with the specific recipient key and stored at the central servers (as *data packets*). Due to asymmetric encryption, the server infrastructure operators are not able to decrypt them. Since each recipient gets their encrypted data, it was necessary to create individual private-public-key pairs for asymmetric encryption.

The following recipients have warranted demands on these packets: two study nurses (to send paper-based questionnaires to the patients), seven health insurance funds (to provide additional *secondary data*), and the University of Bielefeld (UBF) (which gets secondary data, parts of primary data, and questionnaires answers to finally evaluate STROKE OWL). Each of these recipients gets their own data packets.

In ROE, the server-application sends the data packets to their respective recipients for decryption (only they have the needed individual private keys). To avoid the possibility to merge the decrypted packages again (e.g., to re-identify a patient), we proposed in ROE to send a different pseudonym (PSN) for each recipient (so-called *recipient-oriented PSNs*, *ROPSN*). The server-application uses a central PSN for each patient to (1) store the encrypted data packages in a consistent way and (2) for *identity management* - to translate between different ROPSN when needed.

3. Development and system architecture

With the early focus on Privacy by Design, our system design process was heavily driven by data security and safety. Especially the first implementation and later updates for ROE forced us to document and evaluate every single design decision. This led us to two important documents: (1) a detailed description of needed data attributes, formats, transfer protocols, roles and role interaction processes (*data format and transmission concept*) and (2) a *data security and privacy concept*, which describes measures to secure this data in the context of STROKE OWL. After all project partners agreed to these

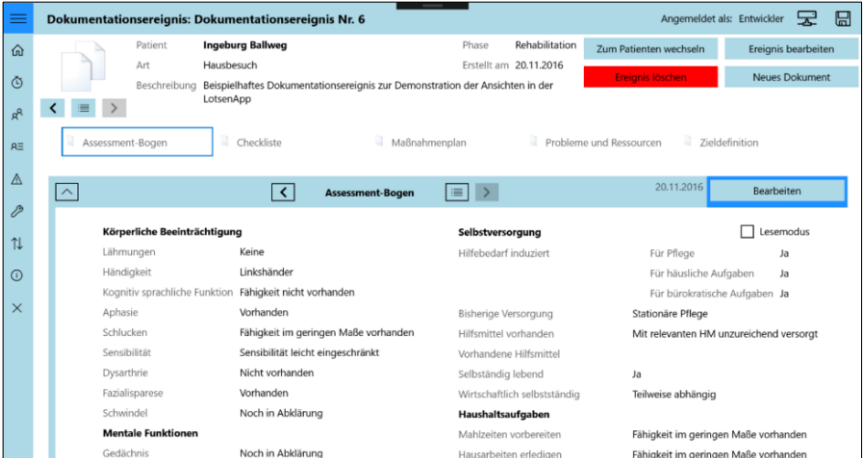

Figure 1: Example screenshot of the LotsenApp (with generated example primary data)

documents and concepts, we designed and implemented our IT system architecture accordingly with ROE in mind (see Figure 2).

Our current architecture is divided into three parts: (1) client application, (2) server application and (3) recipient application(s). The client application *LotsenApp* is used by each stroke pilot (see an example screenshot in Figure 1). It is a graphical user interface which helps the pilots to input primary data fast and easy. We defined well-formed selection lists, added simple plausibility checks, and developed a documentation structure to manage the huge number of different fields needed to fill for each patient. Additionally, the *LotsenApp* contains tools to manage the contact networks of patients, doctors etc. easily.

The *LotsenApp* is the only application which has a reason to access, edit, and delete all primary data. It encrypts (parts of) this data asymmetrically with the individual public keys of all recipients. If the client application has access to the internet, encrypted data packets are sent to the server application.

The *LotsenTablet* is a mobile tablet the *LotsenApp* is running on and allows stroke pilots to access the data at the patients side everywhere (in hospitals, at patients, etc.).

The realization of the server-application is called *DAVE* (Data Vault Environment). *DAVE* (1) manages and distributes public keys for data encryption, (2) stores encrypted data packages for each recipient, and (3) contains the identity management for translating and transmitting PSNs and ROPSNs.

Since the collected primary data in STROKE OWL is essential for the success of this project, we also implemented a three-layered backup system to minimize the possibility of data loss or unintended changes. This procedure is independent to ROE. In the first layer, the *LotsenApp* stores primary data always locally at first (in so called *save states*). Every save state creates a new local file (up to 200 files). With this, stroke pilots can “jump back” to older save states to recover from errors or data loss. If a connection to *DAVE* is available, the *LotsenApp* transmits a backup copy to *DAVE* (second layer to avoid data loss due to hardware failures). Finally, in the third layer, *DAVE* creates backups of all its databases.

To maintain data privacy, all backup copies are symmetrically encrypted with a *data password*, chosen and only known by the specific stroke pilot. Data passwords are also

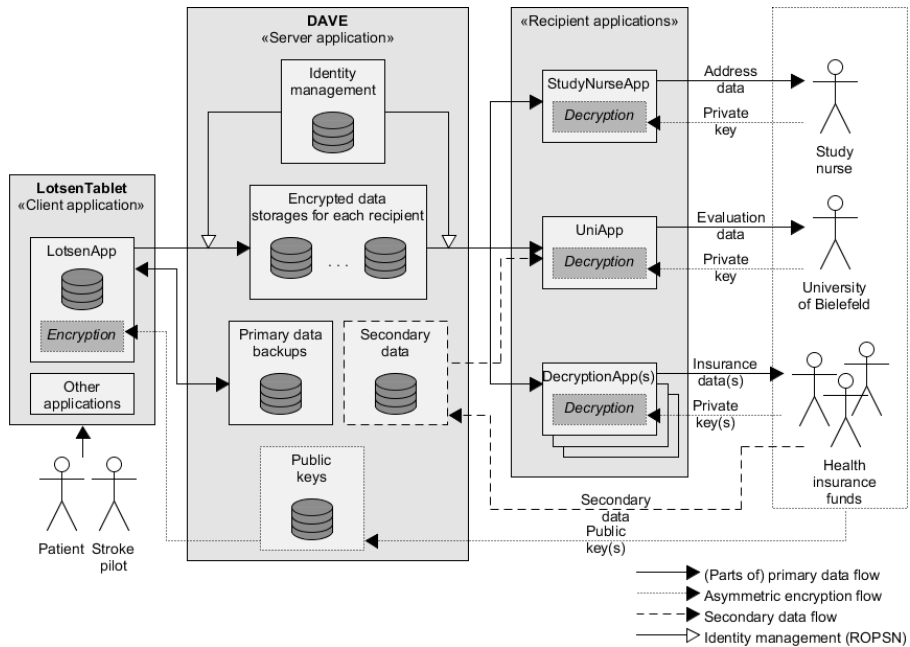

Figure 2: Overview of the IT system architecture in STROKE OWL

independent from our authentication mechanisms. Therefore, each stroke pilot has two passwords: one for authentication and one for their primary data.

Instead of using one central server application for implementing DAVE, we decided to move towards a modular design with multiple, smaller, and independent server applications (connected with REST-APIs and HTTPS). Some of them are the following: primary data backup, authentication and authorization management, identity management (ROE), secondary data management, recipient data package storage (ROE), and data import/export. There is also a mirrored (but separate) server of DAVE (called *staging server*), which allows us to test data loss, connection problems, new developments, changes, and corrections in more realistic environments (integration and system tests). This avoids problems of losing a tablet or a hacking attempt stated in [5].

The recipient applications proposed in ROE are represented by multiple smaller applications in STROKE OWL. In each recipient application, the user (study nurse, UBF and health insurance funds) provides his private key to decrypt the data packages, which were sent from DAVE beforehand. The *StudyNurseApp*, the recipient application for study nurses in STROKE OWL, additionally helps in coordinating the paper-based questionnaires (marks, which questionnaires were sent, received, etc.).

4. Lessons learned

Defining and communicating the data format and transmission concept as well as the data security and privacy concept played a key role in implementing very important security features like asymmetric encryption and ROE. Both documents helped us to communicate with our project partners in technical, organizational, and computational concerns. Especially health insurance funds, who will provide secondary data, needed these descriptions. In similar (health-specific) projects, we strongly encourage to define

these documents beforehand to avoid security-related problems and misunderstandings between different sectors, persons and stakeholders.

Additionally, the three-layered backup system to avoid data loss is beneficial. Despite the fact that backups are necessary measures for data safety, three backup layers also offer a remedy against user-induced, non-grave data loss. Therefore, not every data loss leads to a complete recovery of the entire IT-infrastructure saving time and money.

The generation of receiver-specific key-pairs was more time-consuming and organisationally complicated as expected. For similar projects with many different recipient, we need to dedicate more time for this crucial step. In STROKE OWL, we compensated the time-loss with a developed simple application which creates key pairs automatically. Every recipient created a pair in one minute. For decryption, we provide another application. With this, recipients can use their primary keys to decrypt their encrypted data.

5. Current state and conclusion

We outlined the practical implementation of receiver-oriented encryption on the basis of the STROKE OWL project. Privacy by Design is a complex but important design paradigm especially in health-care. In STROKE OWL, this resulted in our proposed ROE. ROE can be used in similar projects with high data security demands and many data recipients with focus on very strict asymmetric encryption rules. However, due to its organisational complexity with that many project partners, a long planning phase must be considered to avoid later problems. The success of STROKE OWL shows us that this drawback is worth to take: As of January 2020, currently 17 stroke pilots are using the LotsenApp successfully. More than 1200 patients are participating in this project. Two study nurses using the StudyNurseApp. Up to 3200 paper-based questionnaires were sent and filled successfully. The reports from pilots and other users showed high satisfaction and productivity with the applications. We are content with this development and continuously refine and update our applications and components.

^b*City University of New York*

^c*Columbia University, New York, NY, USA*

Abstract. The purpose of this study was to investigate the effect of a telerehabilitation system on the quality of sleep in patients with multiple sclerosis (PwMS). Fifteen females and two males (60.1 ± 11.4 years) who used the system for three months completed the Pittsburgh Sleep Quality Index (PSQI) at the baseline and end of follow-up. Total System Usage (TSU) and Total Exercise Time (TET) were elucidated from the system web logs for each PwMS. A significant association ($p < 0.05$) was found between PSQI sleep efficiency (SE) and TSU (0.76) and between SE and TET (0.81). The association between PSQI total score (TS) and TSU and between TS and TET were -0.507 and -0.702 respectively ($p < 0.05$). Our results uncovered an association between amount of exercise time spent by PwMS and positive effects on both the efficiency and quality of sleep. Thus, further development of approaches promoting continuous participation of PwMS in telerehabilitation is warranted.

Keywords. Telerehabilitation, exercise duration, multiple sclerosis

1. Introduction

Sleep disturbances in people with multiple sclerosis (PwMS) are associated with fatigue, depression, and reduced quality of life [1]. Over 60% of PwMS report impaired sleep quality [2]. In middle-aged and older adults with sleep problems, an exercise program improved the quality of sleep [3]. Current evidence indicates that patients with multiple sclerosis can gain health benefits similar to those from healthy populations through regular exercise [4, 5]. Home-based telerehabilitation has been shown to be well accepted by PwMS [6, 7]. The Home Automated Telemanagement (HAT) system supporting regular multimodal exercise was described previously as promising means to improve mobility and improve quality of life in PwMS [8]. The sustainable impact of remote disease management depends on patient adherence to the program [9]. In addition, high levels of participation, which include proper exercise engagement, facilitate improvements in patients' quality of life, curb the negative effects of fatigue, and improve the quality of sleep. However, the association between extent of

¹ Corresponding Author, Joseph FINKELSTEIN, MD, PhD, Department of Population Health Science and Policy, Icahn School of Medicine at Mount Sinai, New York, NY 10029, USA; E-mail: joseph.finkelstein@mssm.edu.

participation in home-based exercise promulgated by a telerehabilitation system and changes in sleep quality has not been systematically evaluated. The main purpose of this study was to investigate the effects of a telerehabilitation system usage patterns on the quality of sleep in PwMS.

2. Methods

2.1. Systems

The HAT system supporting individualized home-based telerehabilitation in PwMS was used in this study [6]. Following the chronic care model, the HAT system guides PwMS in executing their individualized exercise plans at home, facilitates patient-provider communication and multidisciplinary care coordination as previously described [8]. Tailored motivational messages are provided to enhance adherence [6-8].

2.2. Study design

After being consented as a study participant, PwMS were prescribed an individualized exercise plan based on a comprehensive physical therapy examination by a licensed physical therapist. All patients were trained how to perform exercise at home by the physical therapist and received the necessary exercise equipment. The study participants were asked to use the home-based telerehabilitation system on a daily basis. The system guided them in following their exercise prescription, logged their exercise performance, and communicated exercise logs to their physical therapist who followed up with the patients on as needed basis based on patient performance.

The Pittsburg Sleep Quality Index (PSQI) [10] was used to evaluate self-reported quality of sleep at baseline (BL) and 3-month follow-up (3M). Sleep quality was characterized by four PSQI factors: sleep efficiency, sleep disturbances, daytime dysfunctions, and total score.

The patterns of telerehabilitation system usage including extent of regular exercise completion over the 3-month period were elucidated based on daily web-based logs. The web logs were automatically generated by the HAT system which included time stamps for each web page visited by the telerehabilitation system users. Based on these logs, the following telerehabilitation usage indicators were calculated:

- Total system usage time: total system usage time over 3-month period from BL to 3M
- Daily usage time: average time spent with the system on the days when a user logged in (users could log in multiple times during a single day)
- Visit usage time: average time spent with the system for each separate log-in instance
- Average percent of sets completed: average percent of exercise sets completed out of all sets prescribed for a daily exercise program
- Total exercise time: total time spent in an exercise mode in the telerehabilitation during the 3-month period from BL to 3M

The system usage indicators provided insights on how different patients used the telerehabilitation system and how much time they devoted to the prescribed exercise

program. Associations between the PSQI scores and system usage indicators were analyzed using IBM SPSS Statistics 26 for Windows. Association between study variables (r) was assessed using Pearson correlation coefficient.

3. Results

3.1. Socio-demographic characteristics of patients

Overall, 3-month telerehabilitation data from seventeen PwMS were analyzed (15 females and 2 males). The average patient age was 60.1 ± 11.4 ranging from 39 to 76 years old; 70.6% of the participants were Whites and 11.8% were Hispanics; average duration of education was 15.5 ± 2.7 years. The time since multiple sclerosis diagnosis varied between 2.5 and 50.8 years and the average of education was. Self-assessed disease severity was reported as severe by 11.2% of participants; 29.4% reported that their disease is progressing (Table 1).

Table 1. Socio-demographic Characteristics of Patients

Characteristics (yrs.)	Minimum	Maximum	Mean	SD
Age	39	76	60.1	11.4
How long have MS	2.5	50.8	26.0	13.5
School	10	20	15.5	2.7
Characteristics	Gender	Race	Hispanic	
No. (%) (N=17)	female	AA	3(17.6)	yes
		Asian	2(11.8)	
	Male	white	12(70.6)	no
				15(88.2)
Characteristics	MS severity	Disease		
No. (%) (N=17)	Mild	5(29.4)	progressing	5(29.4)
	moderate	10(59.8)	stable	11(94.1)
	severe	2(11.2)	improving	1(5.9)

yrs.: years, MS: multiple sclerosis, SD: standard deviation, AA: African American

3.2. PSQI and system usage patterns

Average changes between BL and 3M for PSQI sleep efficiency, PSQI sleep disturbances, PSQI daytime disturbances, and PSQI total score were -0.1, 0.9, 0.5 and 0.2 respectively (Table 2).

The total time that PwMS spent using the HAT system over the 3-month follow-up period ranged between 6 and 68 hours with average time of 30.7 ± 19.8 hours. The mean total time patients spent with a system on a day when they logged-in was 26.5 minutes, and the average total time patient spent at each single sign-in visit was 22.0 minutes. The patients' average percentage of completed exercise sets and prescribed number of exercise repetitions were 46.5% and 72.6% respectively, and the average total time spent in the exercise mode was 13.5 hours (Table 2).

3.3. Bivariate correlations

Pair wise associations between nine sleep quality and system usage parameters were investigated including 4 PSQI scores and 5 usage pattern indicators. The association between PSQI sleep efficiency and Total system usage time and between PSQI sleep

efficiency and Total exercise time were 0.757 and 0.814 respectively. The association between PSQI total and Total system usage time and between PSQI total and Total exercise time were -0.507 and -0.702 respectively. Correlation between Daily usage time and Visit usage time was 0.910 and r between Total system usage time and Total exercise time was 0.886. The r between PSQI sleep efficiency and PSQI total was 0.722.

Table 2. PSQI scores, PSQI changes in 3 months, and system usage indicators

Parameter name	Minimum	Maximum	Mean	SD
PSQI sleep efficiency (BL)	57	100	84.7	12.6
PSQI sleep efficiency (3M)	56	120	84.5	16.2
PSQI sleep efficiency (3M-BL)	-23.3	38.3	-0.1	15.9
PSQI sleep disturbances (BL)	1	11	6.4	3.3
PSQI sleep disturbances (3M)	3	18	7.3	4.1
PSQI sleep disturbances (3M-BL)	-6	8	0.9	4.6
PSQI daytime dysfunctions (BL)	0	3	1.0	1.0
PSQI daytime dysfunctions (3M)	0	4	1.5	1.4
PSQI daytime dysfunctions (3M-BL)	-1	3	0.5	1.1
PSQI total (BL)	1	11	6.7	2.8
PSQI total (3M)	2	14	6.9	3.4
PSQI total (3M-BL)	-6	3	0.2	2.3

Daily usage time (sec)	311.5	4,258.3	1,588.2	947.9
Visit usage time (sec)	307.1	2,248.8	1,324.8	601.0
Average percent set completed (%)	69.4	142.0	97.8	17.7
Total exercise time (sec)	7,489	157,502	48,457.2	45,499.8

SD: standard deviation, BL: data acquired at the baseline, 3M: data acquired at the 3-month follow-up, 3M-BL: difference in PSQI score between 3M and BL

Table 3. Correlation matrix between PSQI score changes and system usage indicators

Parameter name								
A. PSQI sleep efficiency (3M-BL)	A							
B. PSQI sleep disturbances (3M-BL)	-0.041	B						
C. PSQI daytime dysfunctions (3M-BL)	0.562	0.362	C					
D. PSQI total (3M-BL)	-0.722	0.248	-0.105	D				
E. Total system usage time (sec)	0.757	0.085	0.400	-0.507	E			
F. Daily usage time (sec)	0.536	-0.109	0.490	-0.240	0.588	F		
G. Visit usage time (sec)	0.532	-0.153	0.306	-0.302	0.596	0.910	G	
H. Average percent set completed (%)	0.102	-0.255	-0.047	0.166	-0.098	0.135	0.278	H
I. Total exercise time (sec)	0.814	0.127	0.321	-0.702	0.886	0.369	0.436	-0.114

All values represent the Pearson correlation coefficient (r), light gray cells have p value<0.05 and dark gray cells have p-value<0.01, BL: data acquired at baseline, 3M: data acquired at the 3-month follow-up, 3M-BL: score difference between 3M and BL

Figure 1. Comparisons between the enhanced group and the degenerated group

Table 4. Comparison between sleep improvement and deterioration groups (mean ± standard deviation)

Group	TSU	TET	ΔSE	ΔTS
Sleep Improvement	38.6±20.9	19.7±14.5	12.7±12.7	-1.4±2.0
Sleep Deterioration	22.0±15.2	6.4±4.1	-11.6±7.3	2.0±0.8

TSU: total system usage in 3 month (hours), TET: total exercise time in 3 month (hours),
ΔSE: change in PSQI sleep efficiency score, ΔTS: change in PSQI total score

4. Discussion

In this study, we used the a telerehabilitation system supporting an individualized multimodal exercise prescription to investigate how system usage patterns are associated with sleep quality. Our results indicate the accumulation of the system usage time has a positive effect on both the efficiency and quality of sleep. In particular, the accumulation of exercise time had a greater impact on PSQI scores (Table 4). We found that there was a significant difference in the total exercise time between the PwMS with improved or unchanged sleep efficiency and those whose sleep efficiency deteriorated ($F=8.570$, $p=0.010$). Similarly, there was a significant difference in the total exercise time between the group of patients with improved or unchanged total quality of sleep (PSQI total) and the group of patients whose total sleep quality score deteriorated over 3-month follow-up period ($F=6.247$, $p=0.024$) as depicted in Figure 1.

Based on the results from 3-month telerehabilitation, improvements in sleep quality were associated with approximately 9.3 hours of total exercise time which is an equivalent of at least 20 minutes of exercise twice a week. Our data strongly support positive impact of telerehabilitation on PwMS who might otherwise have difficulty traveling to an outpatient program. Further work to enhance PwMS participation in telerehabilitation is warranted.
